# AEROSOL DRUG DELIVERY TO THE LUNGS

Andrew R. Martin and Warren H. Finlay
*Department of Mechanical Engineering, University of Alberta Edmonton, Alberta, Canada*

## 1 INTRODUCTION

The delivery of therapeutic agents locally to the lungs through the inspiratory route is, in the majority of cases, the preferred course of treatment of respiratory diseases. Indeed, inhaled aerosols have long been employed in the management of asthma, cystic fibrosis, and chronic obstructive pulmonary disease (COPD). Gas-borne suspensions of fine liquid droplets or solid particles are introduced into the patient's inspiratory airflow to carry drugs into the lungs. Over recent years, it has become apparent that systemic drug delivery through the lungs to the bloodstream is an attractive alternative to more traditional methods of delivery, such as oral or intravenous administration. Targeting of inhaled aerosols to the lungs' alveolar regions allows for transport of deposited drug across the alveolar epithelium into the capillaries. Accordingly, aerosol drug delivery has emerged as a viable option for systemic administration of a large variety of drugs and will likely play an important role in the development of new therapies over the next decade.

The development and evaluation of aerosol drug delivery systems requires a level of comfort with fields such as aerosol mechanics, fluid mechanics, and transport phenomena that may be unfamiliar to newcomers whose training backgrounds lie outside of the physical sciences. The intent of the first section of this chapter is to provide a very brief introduction to aerosol mechanics as related to the transport and deposition of inhaled drug particles throughout the respiratory tract. This familiarization will serve as requisite background for the discussion of aerosol particle sizing instruments in use for research and development, regulatory, and quality assurance purposes, as well as for descriptions of the different types of aerosol delivery systems currently available and in development.

## 2 RESPIRATORY TRACT DEPOSITION OF INHALED PARTICLES

The human respiratory tract is made up of a complicated series of branching, or bifurcating, airways. Phillips et al. [1] have described in detail much of the influential work done in measuring and modeling respiratory tract geometry. Despite its limitations, the most widely adopted model remains the highly idealized, symmetric model given by Weibel [2], and referred to as the Weibel A model. Under the Weibel A model, airways are classified by a generation number (beginning with zero at the trachea), which indicates the number of bifurcations separating the airway from the trachea. Airway diameters and lengths become progressively smaller as the generation number increases. Generations 0–16 make up the tracheobronchial region, through which air is conducted upon inhalation and exhalation, while generations 17–23 comprise the alveolar region, wherein gas exchange with the capillaries occurs. In addition, the extrathoracic region, consisting of the oral and

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad

nasal cavities, the pharynx, and the larynx, must be included in a complete description of the respiratory tract. Further discussion of respiratory tract structure and function, in the context of aerosol drug delivery, may be found in ICRP Publication 66 [3], in Altiere and Thompson [4], in Finlay [5], and in Stocks and Hislop [6].

The site within the respiratory tract at which an inhaled particle deposits is a key determinant of its subsequent pharmacokinetics. For topical treatment of certain lung diseases, it may be preferable to target the tracheobronchial airways, while for systemic delivery to the bloodstream, deposition deep into the alveolar region is required. Deposition in the extrathoracic region is undesirable for pulmonary delivery, so that these upper airways are viewed as a barrier that filters out particles intended to reach the lungs.

The size and mass of an inhaled particle affect its entrainment in inspiratory and expiratory airflow, thereby encouraging deposition in particular regions of the respiratory tract. For this reason, it is the convention in aerosol science to express particle size and mass in terms of an *aerodynamic* diameter, given as

$$d_{ae} = \sqrt{\frac{\rho_{particle}}{\rho_{water}}} d \tag{1}$$

where $d_{ae}$ is the particle aerodynamic diameter, $d$ is the particle geometric diameter, $\rho_{particle}$ is the density of the particle, and $\rho_{water}$ is the density of water.

For irregular particles, the aerodynamic diameter standardizes shape to that of a sphere and density to that of water. The assumption of spherical shape is in general reasonable, given that liquid droplets *will* be spherical due to surface tensions, while solid particles are usually compact, so that their motion through the air is not too much different from that of a sphere of equivalent volume.

Figure 1 displays average total respiratory tract deposition of inhaled aerosol particles as a function of aerodynamic diameter for three different breathing patterns, as measured by Stahlhofen et al. [7] in human subjects during tidal mouth breathing. A broad minimum of total deposition exists around aerodynamic diameters of about 300 or 400 nm. As the curve rises to the left and right of the minimum value, deposition tends to shift toward more proximal (i.e., closer to the mouth) regions of the respiratory tract. For example, particles larger than approximately 5 μm deposit primarily in the mouth, throat, and upper branches of the bronchial tree. The shape of the total deposition curve can be understood through consideration of the different physical mechanisms through which respiratory tract deposition occurs, as will now be introduced.

**Figure 1** Total respiratory tract deposition of inhaled particles as a function of the aerodynamic particle diameter for human subjects during tidal mouth breathing. Three different breathing patterns are shown. (From Stahlhofen et al. [7].)

**Figure 2** Illustration of particle deposition by inertial impaction.

## 2.1 Factors Determining Deposition

***Particle Inertia*** Aerosol particles are carried into the lungs by inhaled airflow. Where air streamlines (i.e., lines everywhere tangent to the air velocity) are curved at bends in the respiratory airways, aerodynamic drag forces act on the particles to steer them along with the flow, around the bends. However, a particle's inertia can cause it to deviate from a streamline to the extent that it deposits on an airway wall, as illustrated in Figure 2. The situation can be thought of as analogous to an automobile that veers off the road as a result of traveling too quickly while attempting a sharp turn. The ratio between particle inertia and the drag force is described by the particle Stokes (Stk) number:

$$\mathrm{Stk} = \frac{U\rho_{\mathrm{particle}} d^2 C_C}{18\mu D} \tag{2}$$

where $U$ is the average air velocity in the airway, $\mu$ is the air viscosity, $D$ is the airway diameter, and $C_C$ is the Cunningham slip correction factor, which accounts for the fact that very small aerosol particles experience a reduced drag force owing to their ability to "slip" through spaces between gas molecules. For particles a few microns and larger in diameter, a typical size range for inhaled drug particles, $C_C$ is very close to unity and can be dropped from Equation (2) with little consequence. Further discussion of the slip correction factor for small aerosol particles can be found in Willeke and Baron [8] or in Hinds [9].

From the value of the Stokes number, it is possible to qualitatively describe the motion of aerosol particles through the airways. For Stk << 1, the drag force largely suppresses any particle inertia, and particle trajectories follow air streamlines very closely. However, as Stk grows larger, the relative influence of inertia on particle motion grows stronger, and particle trajectories increasingly stray from curved streamlines. Accordingly, numerous experimental and numerical studies indicate that the probability of inertial deposition of an inhaled particle on airway walls increases monotonically with the Stokes number [3, 10–17]. A summary and comparison of various formulas available in the literature to relate the probability of inertial deposition in the respiratory tract to the particle Stokes number can be found in Finlay [5]. In the interest of brevity, it is enough at present to note from Equation (2) that the Stokes number, and therefore the likelihood of inertial deposition, increases with the average air velocity, the particle density, and the square of the particle diameter. The latter, squared dependence indicates the strong effect of particle size on inertial deposition. The fact that the probability of inertial impaction also increases with air velocity leads to the conclusion that impaction occurs primarily in the mouth, throat, and upper generations of the tracheobronchial region, where flow rates are highest. Particles with aerodynamic diameters of approximately 10 μm and larger are predominantly filtered by inertial impaction in the extrathoracic region, and thus do not normally reach the lungs for typical inhalation flow rates. The bifurcating structure of the respiratory tract ensures that air velocities deep in the lungs are orders of magnitude smaller than those at more proximal levels, thereby very much reducing the probability that inertial impaction will occur into the alveolar region. However, for a given air velocity, the Stokes number increases with decreasing airway diameter. Such a relationship highlights the dependence of inertial deposition on an individual patient's respiratory tract geometry, which is responsible in part (along with variations in breathing maneuver) for large intersubject variability in extrathoracic and tracheobronchial deposition patterns [7].

***Gravitational Sedimentation*** Aerosol deposition in the respiratory tract can also occur when the influence of gravity causes particles to settle onto airway walls. The likelihood that a particle will deposit due to gravitational sedimentation will increase with its settling velocity, which is the terminal velocity of the particle in still air. The settling velocity may be expressed as

$$v_{\mathrm{settling}} = \frac{C_C \rho_{\mathrm{particle}} d^2 g}{18\mu} \tag{3}$$

where $g$ is the acceleration due to gravity. Finlay [5] has demonstrated that by approximating the respiratory airways as randomly orientated cylindrical tubes, it can be determined that the probability of particle deposition in an airway by sedimentation increases monotonically with the nondimensional parameter $t'$, given as

$$t' = \frac{v_{\mathrm{settling}} L}{UD} \tag{4}$$

where $L$ is the airway length. This result is comparable to that of previous researchers, where a parameter similar to $t'$, but including the angle of airway orientation, was employed [18, 19].

Equation (4) can be thought of as a ratio comparing the average residence time of a particle in an airway ($L/U$) with the approximate time required for the particle to settle onto an airway wall ($D/v_{\mathrm{settling}}$). For $t' \ll 1$, the particle passes through the airway in much less time than would be required for it to deposit by gravitational sedimentation; however, as $t'$ increases, so does the probability that the particle will come to rest on a wall prior to leaving the airway. As was the case for inertial deposition, the probability of deposition due to sedimentation increases with the particle density, and the square of the particle diameter (both of which increase the settling velocity). Conversely, the likelihood of sedimentation onto airway walls decreases with the average air velocity, an opposite trend to that discussed above for inertial deposition. As a result, deposition by sedimentation primarily occurs deep in the lungs, where air velocities are sufficiently low to give particles time to settle onto airway walls. It is important to note here that while Equations (3) and (4) indicate that the probability of deposition by sedimentation is greater for larger particles, particles exceeding a certain size (aerodynamic diameter of about 5 μm) will likely be filtered out in the

extrathoracic region and the upper part of the tracheobronchial region by impaction prior to reaching the bronchioles and the alveolar region where sedimentation is favored. This regional filtering will be discussed in more detail later; however, it can now be stated that the combined actions of gravitational sedimentation and particle inertia are responsible for the increase in total respiratory tract deposition with increasing aerodynamic particle diameter that occurs to the right of the minimum value as displayed in Figure 1.

***Brownian Diffusion*** The motion of very small aerosol particles (with diameters much less than 1 μm) is influenced by random collisions with air molecules. The trajectories of such particles change direction sharply at the occurrence of a collision and as a result are nondeterministic. This type of random-walk particle path is known as Brownian motion. Over time, Brownian motion can cause very small aerosol particles to diffuse onto airway walls, as is illustrated in Figure 3.

While the exact paths followed by particles subject to Brownian motion cannot be predicted, it is possible to estimate the net distance over a given time that a particle will be displaced due to molecular collisions. As such, the average deposition probability of particles in a cylindrical tube can be determined [20–23] and has been shown to increase monotonically with the parameter

$$\Delta = \frac{kTC_C}{3\pi\mu d_{\text{particle}}}\frac{L}{UD} \tag{5}$$

where $k = 1.38 \times 10^{-23}$ J/K is Boltzmann's constant, and $T$ is the air temperature expressed in kelvins. As was the case for gravitational sedimentation, the probability of deposition due to diffusion increases with decreasing air velocity; therefore, diffusional deposition might be expected to occur deep in the lungs, in the alveolar region. This is a reasonable assumption for particles no smaller than 100 nm; however, notice that the probability of particle deposition by diffusion increases with decreasing particle size, whereas the probabilities of deposition by impaction and sedimentation both increased with the square of particle diameter. Referring back to the total deposition curve displayed in Figure 1, deposition that occurs to the left of the minimum value results from Brownian diffusion. In the extreme case for particles less than 10 nm in diameter, total respiratory tract deposition can reach values over 90%, and as these particles are rapidly transported to airway walls by random collisions with air molecules, significant fractions of the particles deposit in the extrathoracic and tracheobronchial regions.

**Figure 3** Illustration of particle deposition by Brownian diffusion.

In aerosol drug delivery, diffusional deposition normally plays a minimal role. Typical pharmaceutical aerosols consist of particles a few microns in diameter, for which diffusive motion is largely negligible. Even when these aerosols do contain significant portions of particles with submicron diameters, for the particle size distributions produced by conventional inhalers the majority of the drug dose (by mass) is contained in larger, micron-scale particles.

***Electric Charge*** Aerosol particles produced by conventional delivery devices can contain significant amounts of electric charge [24–28]. As many devices are made from plastics that are typically susceptible to carrying surface charge, electrostatic effects can lead to aerosol deposition in the devices, reducing their output efficiencies [29]. Care must also be taken in performing bench tests of delivery devices so that any electrostatic effects occurring in plastic airway replicas are accounted for [30].

In the respiratory tract itself, analyses by Yu [31] and by Finlay [5] predict that the charge on aerosol particles must reach quite high levels before electrostatics plays a significant role in determining deposition. These analyses appear to be in good agreement with experimental measurements [32], though the possibility that high humidity in the respiratory tract mitigates electrostatic effects even further remains to be fully evaluated [5]. Many aerosols produced for drug delivery contain charges well below the levels predicted by Yu [31] and Finlay [5], so that electrostatic effects are not expected to influence deposition in the lungs for these aerosols. However, certain pharmaceutical aerosols [25] do contain high enough charge that deposition might be affected; therefore, electrostatic effects should be considered on a case-by-case basis.

## 2.2 Regional Deposition

***Mouth–Throat Deposition*** Whether the intention is to target deposition of an inhaled therapeutic aerosol to the tracheobronchial airways for treatment of lung

disease or to the alveolar region for systemic delivery to the bloodstream, deposition in the mouth and throat is rarely desirable. Deposition in the mouth–throat region (also referred to as the upper airways, or the extrathoracic or oropharyngeal region) not only reduces the dose delivered to the lungs but can also lead to undesirable side effects, both those that occur locally in the mouth and throat and systemic effects that can occur subsequent to swallowing. While the filtering efficiency of the oral cavity (the mouth) is lower than that of the nasal cavity, the combined geometry of the mouth, the oropharynx, and the larynx still presents a formidable barrier to lung delivery. Airway constrictions in the oropharynx and the larynx cause local acceleration of inhaled airflow and lead to inertial deposition of aerosol particles. In addition, deposition in the mouth is often augmented by drug delivery devices, particularly when aerosol exits the device mouthpiece at high speed. Mouth–throat deposition for commercial inhalers can often reach values higher than 75% of the dose emitted from the device [33–37].

Empirical correlations for predicting average mouth–throat deposition for given particle sizes and breathing conditions are available from multicenter in vivo studies of tidally inhaled aerosols [7, 38]. As is seen in Figure 4, intersubject variability around average deposition curves is very high [7], in large part owing to differences between individuals in mouth–throat geometry [39, 40]. Grgic et al. [40] have presented a correlation that allows for prediction of mouth–throat deposition in a given individual provided that the volume and path length of the mouth–throat airway are known. These correlations [7, 38, 40] are based on experimental data obtained with aerosols supplied to the mouth through straight, relatively large-diameter (~15–25 mm) tubes. In contrast, some delivery devices have smaller-diameter mouthpieces, which can increase deposition in the oral cavity [41–44]. DeHaan and Finlay [45] have presented a correlation that may be used to predict mouth–throat deposition for such devices where the mouthpiece diameter affects deposition.

**Figure 4** Fraction of inhaled particles depositing in the mouth–throat (extrathoracic) region as a function of $d_{ae}Q$, where $d_{ae}$ is the aerodynamic particle diameter and $Q$ is the inhalation flow rate, for human subjects during mouth breathing. The solid line represent an empirical fit to the average of all data points, while the dashed lines represent the approximate range of the data. (From Stahlhofen et al. [7].)

***Lung Deposition*** Deposition in the lungs can be broadly divided into tracheobronchial and alveolar fractions. The tracheobronchial airways are covered with a surface layer of mucus, which sits atop of cilia attached to the airway walls. The cilia beat so as to set the mucus layer in continuous motion toward the throat. Thus, inhaled particles that deposit in the tracheobronchial region are cleared relatively quickly (within approximately 24 h) to the throat, where they are swallowed or expectorated. For this reason, in determining regional deposition patterns in human subjects, researchers typically associate the fast clearing deposition fraction of an inhaled aerosol (i.e., the fraction of total deposition that is cleared within 24 h) with the tracheobronchial deposition fraction. It is important to note, however, that the two are not precisely synonymous, as a small portion of tracheobronchial deposition is not cleared from the region within 24 h, particularly for particles a few microns or less in diameter [3].

The mucociliary clearance mechanism does not extend to the alveolar region. Slow-dissolving aerosol particles that deposit in the alveolar region will persist for much longer than 24 h, and may be subject to a variety of fates, but they are generally thought to be engulfed by alveolar macrophages and phagocytized and absorbed, or translocated to the mucociliary escalator, or the lymphatics [3, 46, 47]. Again, while experimentally determined slowly cleared fractions of inhaled aerosols may be associated with alveolar deposition, a small percentage of particles depositing in the tracheo bronchial airways will remain in the lungs for longer than 24 h.

Figure 5 displays average fast and slow clearing deposition efficiencies of radio-labeled aerosol particles measured in human subjects during oral, tidal breathing as summarized by Stahlhofen et al. [7]. These data were collected with a straight tube inserted into the mouth, so that the mouthpiece effects that can occur for some delivery devices, as discussed in the previous section, are not included. A broad maximum in deposition efficiency occurs for both

**Figure 5** Deposition efficiencies measured in human subjects during tidal mouth breathing for (A) particles cleared from the lungs within 24 h from inhalation, and (B) particles remaining in the lungs after 24 h from inhalation. The solid curves represent empirical fits to the average of the data, while the dashed curve in (A) is an average of the data from Lippman [48] and Chan and Lippmann [12]. (From Stahlhofen et al. [7].)

regions of the lung, with maximum tracheobronchial deposition at approximately 6 µm particle diameter and maximum alveolar deposition at approximately 3 µm particle diameter. As alluded to earlier, tracheobronchial deposition decreases with particle size above 6 µm or so as more and more particles are filtered out by the mouth and throat; likewise, alveolar deposition decreases above 3 µm due to regional filtering by the bronchial airways. While Figure 5 displays general regional deposition patterns averaged over a variety of subjects and tidal breathing conditions, these patterns may shift when specific breathing maneuvers are employed, as can occur with some aerosol delivery techniques. For example, researchers have attempted to improve targeting of pharmaceutical aerosols to specific lung regions through insertion of a short burst (bolus) of aerosol into the inhaled airflow at a prescribed point in the breathing cycle [49–51]. In addition, the data presented in Figure 5 were collected with stable aerosols that, unlike some pharmaceutical aerosols [52–54], do not undergo hygroscopic size changes during transit through the humid respiratory tract. Accordingly, it is best to view the curves presented in Figure 5 only as rough guidelines for estimating regional deposition patterns for inhaled pharmaceutical aerosols.

## 2.3 Deposition Modeling

One of the main benefits provided through an understanding of the mechanics of inhaled aerosols is the ability to predict the behavior and deposition pattern of a given aerosol in the respiratory tract. Deposition models vary greatly in their complexity and in the refinement of their predictions. While many bench tests are performed simply to estimate the fraction of aerosol filtered by the mouth and throat compared to that reaching the lungs, sophisticated computational simulations at times go so far as to determine localized deposition patterns within a single airway bifurcation. Clearly, the choice of type of model to employ depends on the requirements of a particular research or development program. Nevertheless, even in their simplest forms, deposition models can prove extremely useful both in guiding the early, preclinical stages of a project and afterward in evaluating contending explanations of in vivo results.

***Empirical and Semiempirical Models*** Perhaps the simplest models for predicting respiratory tract deposition are purely empirical models. Such models provide a set of algebraic equations fit to a given collection of in vivo experimental data and allow for estimation of regional deposition patterns based on parameters that were varied in vivo, such as particle size and breathing pattern. Empirical models are inherently limited by their inapplicability outside of the parameter space of the experimental data upon which they were based. As the dynamical equations of particle and fluid motion are not explicitly considered in formulating predictive algebraic equations, those latter equations do not lend themselves well to inclusion of dynamical effects such as hygroscopic particle size changes. That said, provided that they are not used outside of their range of applicability, empirical models can facilitate quick, accurate estimation of respiratory tract deposition. Examples of empirical models presented in the archival literature

include those of Davies [55], Rudolf et al. [38, 56], Yu et al. [57], and the ICRP [3].

A level up in complexity from purely empirical models are the so-called dynamical or semiempirical models. Such models predict deposition in a given lung generation through consideration of the underlying physical mechanisms of sedimentation, diffusion, and inertial impaction but may still rely on empirical correlations to estimate the probability of deposition due to a given mechanism (most often, deposition probabilities for sedimentation and diffusion are estimated analytically, whereas the deposition probability for inertial impaction is calculated from empirical correlations). In addition, empirical correlations are employed for predicting mouth–throat deposition. Methods of combining deposition probabilities for individual mechanisms into a combined deposition probability for a given lung generation have been investigated by several authors [3, 58–61].

Dynamical models allow for examination of aerosol deposition in conditions for which experimental data may be sparse. Several authors have incorporated hygroscopic particle size changes into dynamical deposition models [15, 62, 63]. Koblinger and Hofmann [19] have employed stochastic techniques to model asymmetric airway branching. Finlay et al. [64] have combined a dynamical deposition model with a mathematical model of the mucous thickness throughout the tracheobronchial region in order to predict the mucosal drug concentration in each generation. This model has been useful in evaluating the potential efficacy of inhaled antimicrobial agents [65–67], for which local drug concentrations upon delivery may be compared to the minimum inhibitory concentrations of bacteria causing respiratory infection. In addition, regional deposition patterns in infants and children have been modeled by various researchers [3, 64, 68–71] with both dynamical and empirical models, where the idealized lung geometry has been scaled according to age. Detailed review and classification of numerical models for predicting regional respiratory tract deposition for pharmaceutical aerosols may be found in Swift [72] and in Finlay [5, 73].

***Computational Fluid Dynamics*** Use of computational fluid dynamics (CFD) routines has become widespread in recent years over a large variety of industries. Partial differential equations governing fluid motion are discretized over a physical domain of interest and solved iteratively for a given set of boundary conditions to yield the fluid velocity at each point in the domain. Particles may then be numerically introduced and tracked through the domain through consideration of the dynamical particle equation of motion. Given the complexity of the algorithms contained in commercially available CFD software packages, errors in modeling can easily occur if the choice of simulation parameters is not made carefully. Furthermore, user-specified boundary conditions can dramatically affect the computational output. For these reasons, results garnered from CFD simulations should always be validated against experimental data to as best an extent as is possible.

In the context of inhaled aerosols, despite its potential pitfalls, CFD has proven useful in examining aerosol transport and predicting localized deposition to a very fine resolution in geometries such as the mouth–throat region [74–77] and airway bifurcations [78–82]. CFD has also been used in evaluating the design of specific pharmaceutical aerosol delivery devices [83–85]. In product development programs, this latter application of CFD can markedly reduce the time and cost required for evaluation of several prototypical designs.

***Bench Tests*** In many instances, aerosol drug delivery systems involve physical phenomena that are not understood or not characterized to the extent that they can be described by mathematical equations in dynamical or CFD models. Examples include the deagglomeration of powders; aerodynamic breakup and two-way coupled evaporation of droplets in ballistic sprays; triboelectric charging and resultant electrostatic effects; and homogeneous or nucleated condensation of supersaturated vapors. In these circumstances, researchers must turn to bench tests to evaluate the performance of the devices. Such tests also play a role in the regulatory process and are used in batch testing for quality control of aerosol products.

One of the most intuitive, and most useful, tests that can be performed *in vitro* on the bench is to collect the aerosol mass delivered to a filter placed distal to a replica of the extrathoracic airways. In such a manner, the fraction of the dose delivered to the lungs may be estimated. Figure 6, from Dolovich and Rhem [86], displays seven different "throats" that have been used for this purpose. Of these, the USP-1, USP-2, and twin impinger inlet have been the most popular [87]. Unfortunately, these inlets do not accurately represent the complex geometry of the mouth and throat, and are known to underpredict mouth-throat deposition [88, 89]. Replicas based on casts or images of individual mouth-throat geometries are more realistic, but their lack of generality, especially considering the large intersubject variability in mouth-throat deposition, is problematic. For these reasons, it is desirable to have an idealized mouth-throat model that matches average *in vivo* deposition data. For adult subjects, one such idealized geometry is the Alberta geometry, as displayed in Figure 7, which has been shown to match average *in vivo*

**Figure 6** Sagittal views of seven different throat models. (From Dolovich and Rhem [86].)

**Figure 7** Sagittal view of the Alberta mouth–throat geometry. (From DeHaan and Finlay [44].)

data for inhalation flow rates typical to many aerosol delivery devices [40, 44, 90].

A second approach to bench testing of aerosol delivery devices is to determine the distribution of particle sizes exiting the device mouthpiece and then to predict regional deposition patterns using either empirical or dynamical models such as those described above or using correlations developed for specific classes of device. In the latter approach, deposition is usually correlated with the fraction of the aerosol mass contained in particles below some cut-off diameter. This fraction is termed the respirable fraction or the fine-particle fraction. Clark and Borgstrom [87] review some of the correlations that have been developed for commonly used delivery devices. Given that these predictions are dependent on accurate determination of the particle size distribution delivered from the device, it is prudent to review several aerosol sizing instruments that have

found application in the pharmaceutical industry. This is the focus of the next section.

## 3 PARTICLE SIZING

The size of an inhaled particle is key in determining its site of deposition within the respiratory tract. Accordingly, much effort has gone into developing experimental instruments and procedures suitable for accurate determination of aerosol particle sizes. Unfortunately, the variety of properties exhibited by different pharmaceutical aerosols prohibits the application of any one, standard approach to particle sizing across all types of delivery devices. While the aerosols produced by some devices are stable in size, others are susceptible to hygroscopic growth or shrinkage. Some aerosol particles exit their delivery devices at ballistic speeds, while others are well entrained in inspiratory airflow. Liquid aerosol droplets are spherical due to surface tensions, while solid particles are in general not spherical. All these differences can affect particle size measurement; therefore, in choosing a sizing technique for a particular application, it is important to have a general understanding of the advantages and limitations of the different types of sizing instrument that are available.

### 3.1 Particle Size Distributions

The vast majority of aerosol drug delivery systems produce aerosols that are polydisperse, meaning that particle diameters vary over a fairly wide size range. Such distributions of size are best described by statistical means, typically under the assumption that the particles are spherical. As mentioned above, the assumption of sphericity is met for liquid droplets but not in general for solid particles. However, as it is the aerodynamic properties of pharmaceutical aerosol particles that govern their inertial and gravitational deposition in the respiratory tract, any compact particle (i.e., any particle upon which the aerodynamic drag force is close to that on a sphere) can be reasonably approximated as spherical. Consequently, the aerosols produced by many conventional delivery systems may be approximated as containing spherical particles.

In order to express particle size data statistically, a suitable distribution function must be found. For most single-source aerosols, the lognormal distribution function provides a reasonable fit to experimental data points [9]. Size distributions of pharmaceutical aerosols are conventionally expressed in terms of mass, as it is the deposited mass that constitutes the delivered drug dose. The normalized, lognormal mass distribution may be expressed as

$$m_{\text{normalized}}(x) = \frac{1}{x\sqrt{2\pi}\ln\sigma_g}\exp\left[\frac{-(\ln x - \ln \text{MMD})^2}{2(\ln\sigma_g)^2}\right] \tag{6}$$

where $x$ is the particle diameter, MMD is the mass median diameter (half of the total aerosol mass is contained in particles with diameter below the MMD), and $\sigma_g$ is the geometric standard deviation. Here, $m_{\text{normalized}}(x)\,dx$ gives the fraction of the total mass contained in particles with diameters between $x$ and $dx$. Of the total mass 68% is contained in particles with diameters between MMD/$\sigma_g$ and MMD*$\sigma_g$. A typical normalized lognormal mass distribution is displayed in Figure 8.

**Figure 8** Normalized lognormal mass distribution, with MMAD = 3 μm and GSD = 2. Of the total aerosol mass 68% is contained in particles with diameters between MMAD/GSD and MMAD*GSD.

In many cases, particle size distributions are described in terms of aerodynamic particle diameters, as related to geometric diameters by Equation (1). Where this occurs, the MMD appearing in Equation (6) is replaced by the mass median aerodynamic diameter (MMAD).

The lognormal distribution provides a convenient summary of particle size data: The size distribution is completely described by its MMD and $\sigma_g$. However, the technique through which the distribution function is fit to experimental data can influence how well the actual particle sizes are approximated [91]. Furthermore, some pharmaceutical aerosols, such as those containing aggregate clusters of particles mixed with deaggregated particles, are poorly described by lognormal distributions. In practice, when lognormal distributions are used to describe particle size distributions, measures should be taken to confirm that the distributions fit experimental data reasonably closely.

### 3.2 Inertial Impactors

Given that respiratory tract deposition of an inhaled pharmaceutical aerosol is determined in large part by its aerodynamic properties, it makes sense that the particle size distribution of the aerosol be determined from those same aerodynamic properties. This is indeed the case for a very popular type of size classification, known as inertial impaction. At its simplest, an inertial impactor can consist of a single nozzle and plate, as in Figure 9. The single nozzle/plate combination, or "stage," serves to separate particles above and below a cut-off aerodynamic diameter, the particle diameter for which the probability of collection on the plate is 50%. Particles with aerodynamic diameters larger than the cut-off carry sufficient inertia through the nozzle that their trajectories deviate from the flow streamlines to the point that the particles impact and collect on the plate. In contrast, particles smaller than the cut-off size are steered around the plate by the carrier flow and may be collected on a downstream filter.

In practice, inertial impactors commonly consist of a number of stages aligned in series and are referred to as multistage or cascade impactors. The cut-off diameters of the stages become progressively smaller moving through the device (from the inlet to the outlet), so that the particles collected on any one plate have a size range bounded at the upper end by the cut-off diameter of the previous stage and at the lower end by the cut-off diameter of the present stage. Such a design allows for a polydisperse aerosol entering the impactor to be sorted into a number of relatively narrow size bins. The cut-off diameters of the stages are typically supplied for one or more flow rates by the manufacturer, and for commonly used impactors calibrations for other flow rates are sometimes available in the archival literature. In cases where collected particles might possibly bounce off the impactor plates or be re-entrained from the plates back into the carrier flow (both of which can occur for powder aerosols), the plates should be coated with grease or otherwise wetted [92] in order to mitigate such effects.

**Figure 9** Schematic diagram of a single impactor stage.

In addition to direct sizing of aerosols by aerodynamic particle diameters, an advantage of inertial impactors is that the drug mass deposited on each plate can be determined directly by chemical assay. This is especially important for multicomponent aerosols, such as powders containing inactive carrier particles, or suspensions of drug particles in liquid droplets, where not all particles contain equal proportions of drug [93]. Furthermore, direct measurement of the aerosol mass distribution is advantageous since for most delivery systems the mass contained within a particular size range is closely correlated to the delivered dose.

Two problems that sometimes arise in interpreting size distributions measured by intertial impaction stem from the fact that the measurements are not made in situ, but rather an airstream is diverted through the impactor. Therefore, the size distribution measured by the impactor is not necessarily the same as the size distribution, for example, exiting the mouthpiece of a delivery device. First, a significant fraction of the aerosol can be lost in the inlet port used to draw air into the impactor. For this reason, in testing delivery systems, some of the "throats" depicted earlier in Figure 6 are often used as inlets to inertial impactors, with the interpretation that the losses in the inlet are then representative of losses that might be expected in a patient's mouth and throat. Unfortunately, as discussed in Section 2.3, many of these inlets poorly model average mouth–throat deposition in humans, so that this interpretation is generally not accurate. This issue has been discussed in detail by Mitchell and Nagel [94].

A second problem can arise when the size distributions of unstable aerosols, such as evaporating droplets, are determined by inertial impaction. As the size distributions of these aerosols vary with time, they can be

expected to change in transit to and through the impactor, especially if the impactor is not in thermal equilibrium with the carrier flow. This issue is discussed further in Section 3.4.

Detailed review of the use of inertial impactors in sizing of pharmaceutical aerosols, including descriptions and cut-off sizes of some of the more popular commercially available cascade impactors, can be found in Marple et al. [95], and in Mitchell and Nagel [94].

### 3.3 Laser Methods

Though inertial impaction is the most widely adopted technique for measuring the size distributions of pharmaceutical aerosols, it is not the only technique available. In fact, a large and diverse range of instruments is available for determining the sizes of aerosol particles. Many instruments have been designed to measure aerosols produced during various natural and anthropogenic processes for which particle sizes are outside the range typical for pharmaceutical applications (broadly, 1–10 μm particle diameters); therefore, these will not be discussed at present. Instead, three light-scattering techniques, each of which has found application in the evaluation of aerosol drug delivery systems, will now be described.

***Time-of-Flight Instruments*** Time-of-flight instruments measure the transit time between two laser beams, separated by a known distance, of aerosol particles exiting a region of accelerating flow. The elapsed time between intersection of the particle with the first and second laser beam is correlated with the aerodynamic particle diameter. As with all single-particle counters, the maximum number density of particles in a volume of the carrier flow is limited by coincidence of two or more particles in the measurement space at the same time. For time-of-flight instruments, aerosol number densities produced by common delivery devices can exceed this maximum [96], so that dilution of the aerosol is required. Add-on dilution instruments are available for precisely this purpose; however, particle losses in the diluter must be accounted for or confirmed as negligible.

A second difficulty that arises with time-of-flight instruments is the presence of artificial background, or "phantom," particles at every particle size [97]. Because mass distributions must be calculated from measured number distributions, a very small number of large phantom particles (which contain a much larger fraction of the total aerosol mass) can skew mass distributions toward larger particle sizes. This can be accounted for in postprocessing calculations, which may be included in software packages accompanying commercial instruments. As for any case in which the mass distribution is a calculated quantity, attention should be paid to the steps taken in converting the raw, measured data to the final, reported distribution.

Finally, unlike chemical assay of inertial impactor plates, but like all light-scattering techniques, time-of-flight instruments do not in general discern between active drugs and inactive excipients. For example, where drug particles are suspended in liquid droplets, no distinction can be made between droplets of the same diameter that contain one drug particle, multiple particles, or no particles [98], making accurate determination of the fraction of drug mass contained in a given droplet size range difficult.

Due to the limitations outlined above, time-of-flight instruments are less attractive for use in determining particle sizes produced by aerosol drug delivery systems than are the other instruments described in the present chapter. However, in applications where all that is required is a quick, comparative measure of the particle size distribution from one device to another, such as in batch testing, time-of-flight instruments may be an attractive option [99].

***Phase Doppler Particle Analyzers*** Phase Doppler particle analyzers (PDPAs) measure the spatial frequency of Doppler-shifted light scattered by an aerosol particle that passes through a measurement volume defined by the intersection of two laser beams. A typical PDPA system setup is displayed schematically in Figure 10. The phase difference between frequency signals measured by two photodetectors spaced slightly apart is linearly related to the spherical particle diameter [100]. A third photodetector may be employed so as to overcome a trade-off between system resolution and range and to check for particle sphericity [101]. As particles must be spherical for accurate sizing to occur, PDPAs are most often employed to size liquid droplets. Unlike time-of-flight instruments, the measurement volume of a PDPA is sufficiently small that coincidence does not tend to interfere with accurate sizing of aerosols for the particle number densities typically produced by inhalation drug delivery systems.

A major advantage of PDPAs is that size measurements can be made in situ, without re-directing the flow of aerosol from a device. In situ measurement is especially useful in sizing volatile aerosols, where particle (droplet) sizes change with time [102, 103]. However, because the PDPA measures particle sizes at a precise location in the flow, determined by the intersection of the two laser beams, it is important either to perform measurements at several locations across the flow or to choose one location for which measurements are representative of the overall aerosol size distribution. In

**Figure 10** Diagram of a phase Doppler particle analyzer (PDPA) system. (From Rader and O'Hearn [100].)

addition, as was discussed above for time-of-flight instruments, light-scattering techniques do not in general differentiate between drug (or drug-containing) particles and inactive, excipient particles; therefore, PDPA data must be carefully interpreted in cases where the proportion of drug in aerosol particles is not constant, such as when a drug is suspended in liquid droplets [93].

***Laser Diffraction Instruments*** Unlike the light-scattering techniques described in the previous two sections, where particles are sized one by one as they pass through a small measurement volume, laser diffraction instruments determine an ensemble size distribution of particles passing through a larger measurement region, produced by an expanded laser beam. Particles in the measurement region diffract light at different angles according to their size, with smaller diameter particles diffracting at higher angles. The cumulative effect of diffraction from a large number of particles is the formation of a Fraunhofer diffraction pattern, which when focused through a Fourier lens is visible as a set of concentric circles [104]. A laser diffraction instrument typically measures diffraction patterns using an array of photodetectors and, through a series of fairly complex computations [100], converts these to size distributions.

The algorithm employed by a particular diffraction instrument to calculate size distributions from measured diffraction patterns can strongly affect its accuracy. Some earlier instruments, based solely on Frauhofer diffraction theory, do not account for refraction of light through small liquid droplets or for scattering of light off more than one particle (which may occur when the aerosol number density is high). Corcoran et al. [104] have demonstrated that this type of instrument is inappropriate for measuring the size distributions of droplets produced by commercial nebulizers, whereas newer diffraction instruments, incorporating more complex algorithms, display much greater accuracy.

Laser diffraction instruments quickly and reproducibly determine particle size distributions and may be employed in situ to size volatile droplets as they exit delivery devices. Consequently, laser diffraction has been used widely to measure the sizes of aqueous droplets produced for aerosol drug delivery [105, 106]. As discussed above for other light-scattering techniques, laser diffraction is better suited for sizing of aerosol droplets produced from solution drug formulations, where the proportion of drug in the droplets is constant, than those produced from suspension formulations.

Laser diffraction has also been used extensively to size solid particles, such as those found in pharmaceutical powder formulations. Strictly speaking, such measurements are not rigorously accurate, as the basic principle of laser diffraction is valid for incident laser light impinging on a spherical particle [107], while solid particles are not generally perfect spheres. Application of a spherical model to nonspherical particles will result in unpredictable measurement errors if the shape of the nonspherical particles is not well defined [107a]. For example, a small deviation in particle shape from that of a sphere to a slightly elongated ellipsoid has been shown to significantly affect apparent particle diameters measured by laser diffraction [108]. While these apparent diameters can be interpreted, given prior knowledge of the particle shape, to provide a reasonable indication

of the physical particle dimensions, in many practical applications particles are neither spherical nor of known analytically specified shape but are rather of some unknown, irregular shape. In these cases, laser diffraction instruments are best suited for quality control purposes, whereas inertial sizing techniques should be used to determine equivalent aerodynamic spherical diameters from which to predict deposition patterns in the respiratory tract.

### 3.4 Evaporation and Condensation

In many inhalation drug delivery systems, aerosol is produced through atomization of a solution, or suspension, of drug in an aqueous medium. In these cases, aerosol droplets may decrease in size as they evaporate into the surrounding air, particularly when the output flow from the device mixes with drier ambient air, as occurs during inhalation. If the mass fraction of droplets in a volume of air is small, droplet evaporation can progress until only the drug and any nonvolatile excipients present in the formulation remain, and the rate at which droplet sizes change with time can be predicted from simplified hygroscopic theory [5, 9]. However, when the mass fraction of droplets is relatively large, evaporation increases the water vapor concentration in the air, which in turn slows further evaporation. This type of "two-way coupled" effect stabilizes droplet sizes when the vapor concentration and temperature of the surrounding air reach equilibrium values. A similar effect can occur for growth of droplets (or solid particles) by condensation in humid air, where the vapor concentration in air decreases as droplets grow. Collectively, evaporation and condensation are referred to as hygroscopic size changes. Finlay [53] has presented a method for classifying the type of hygroscopic size change undergone by aerosol droplets, and has demonstrated that for some nebulizers used to produce aqueous aerosols for drug delivery, the mass fraction of droplets produced is sufficiently high that hygroscopic size changes are negligible. That is to say, droplet evaporation increases the vapor concentration in the air so quickly for these aerosols that an equilibrium is established before the droplets significantly decrease in size. In contrast, aqueous aerosols produced by other nebulizers have smaller mass fractions, so that significant hygroscopic size changes do occur before an equilibrium is reached, if one is reached at all [53].

When droplet sizes do change with time, a dilemma exists in developing experimental sizing procedures. Where should the aerosol size distribution be measured, and what does the distribution represent? One approach is to measure droplet sizes as close to the mouthpiece of the delivery system as is possible [103, 105]. The measured droplet size distribution is then easy to interpret as consisting of the initial sizes of droplets as they exit the device, though sizing can only be performed using instruments capable of in situ measurement. A second approach is to sample the aerosol at some downstream position, typically using a cascade impactor (e.g., [109]). Here, care must be taken to ensure that hygroscopic size changes do not occur between the delivery system and the impactor. Furthermore, if the impactor is not cooled to the temperature of the aerosol, heating of the aerosol inside the impactor can lead to droplet evaporation within the instrument itself [110]. If hygroscopic size changes do occur during transit to and through the sizing instrument, the measured size distribution will be different from that delivered to a patient at the mouthpiece of the delivery system.

Droplet size changes also occur for a second type of pharmaceutical aerosol, produced by atomization of a pressurized, volatile propellant. For these devices, known as pressurized metered-dose inhalers (pMDIs, or simply MDIs), droplet evaporation occurs at a much faster rate than for aqueous aerosols. As a result, size measurements for pMDIs are often made under the assumption that the propellant has completely evaporated, and only solid particles (consisting of drug and nonvolatile excipients) remain. It is important to realize that these residual particle sizes cannot be used to predict deposition in the mouth and throat. When a pMDI is actuated into the mouth, the aerosol consists of rapidly evaporating droplets traveling at ballistic speeds. It is these droplet sizes and speeds that primarily determine deposition in the mouth and throat region. Because droplet diameters and speeds rapidly decrease, due, respectively, to evaporation and entrainment in the inhalation airflow, they are difficult to measure [102], and add a great deal of complexity to predictive, mathematical deposition models. For this reason, mouth–throat deposition for pMDIs is most often estimated from bench experiments using physical mouth–throat replicas, while the sizes of residual particles may be used with mathematical models or correlations to predict regional deposition patterns within the lungs.

## 4 AEROSOL DELIVERY DEVICES

In recent years, many new aerosol drug delivery systems have been developed and introduced to the market. In part, this surge in development has been spurred by the desire to deliver new forms of drug to the lungs. Drugs that have been traditionally delivered through the inhalation route, such as bronchodilators and corticosteroids, have large therapeutic windows, so that high intersubject and intrasubject variability in dosing are

tolerated. However, for many drugs not traditionally delivered through inhalation, including inhaled insulin for treatment of diabetes and cytotoxic agents for treatment of lung cancers, dosing must be controlled much more tightly. Consequently, novel aerosol drug delivery platforms have been invented, with the goal of overcoming some of the known shortcomings of the long-established delivery devices that are currently in wide use. It is not anticipated that this next generation of devices will render current devices obsolete any time soon. More likely, as the market for inhaled drugs grows, the range of available delivery systems will grow alongside it.

The following sections will describe several different types of aerosol drug delivery devices (or inhalers) that are presently in use and in development. This is not an exhaustive list, as new technologies are continuously emerging; however, the vast majority of inhalers will fall into one of the categories outlined below. In addition, we have attempted to avoid referring to commercial companies and products but instead to discuss families of similar devices. References are provided wherein discussion of specific commercial devices may be found.

### 4.1 Pressurized Metered-Dose Inhalers

The pressurized metered-dose inhaler (pMDI) was introduced in the mid 1950s (see [111] for a history of the pMDI and other devices) and remains the most widely used aerosol delivery device for treatment of asthma. The popularity of the pMDI stems largely from its portability and low manufacturing cost. On the other hand, the dose delivered to a patient is highly dependent on his or her inhalation technique, and deposition in the extrathoracic airways is often very high. For these reasons, add-on devices such as spacers are often used with pMDIs to improve delivery.

Briefly, a pMDI formulation consists of a suspension, or solution, of drug in a volatile liquid propellant, or mixture of propellants, held under pressure inside a valved canister. A co-solvent may be added to the formulation to enhance drug solubility. In addition, surfactants are typically added in low concentrations in order to stabilize suspensions and lubricate valves. The choice of formulation can have a significant effect on both the shelf life and performance of a pMDI. With the ratification of the 1989 Montreal Protocol, and the requirement to replace ozone-depleting chlorofluorocarbon (CFC) propellants in pMDIs, many conventional formulation techniques required reinventing with alternative propellants. Over time, hydrofluoroalkane (HFA) propellants have emerged as a viable replacement for CFCs. Review of current practices with respect to formulation of HFA pMDIs may be found in Vervaet and Byron [112] and in Smyth [113].

**Figure 11** Schematic diagram of a typical propellant metered-dose inhaler (pMDI).

A typical pMDI design is displayed schematically in Figure 11. The canister is placed inside a plastic actuator, which contains a spray orifice, or nozzle, and mouthpiece. Prior to actuation of the device, an outlet valve at the base of the canister is closed, while a metering valve inside the canister remains open, allowing the metering chamber to fill with a prescribed volume of the formulation (usually on the order of 50–100 μL). When the pMDI is actuated by depressing the canister, the outlet valve opens and the metering valve closes, causing the metered dose to exit rapidly through the nozzle. The flow of propellant through the nozzle generates a spray of volatile liquid droplets traveling at high velocities. The mechanics underlying this initial spray formation are complex but have been described in as much detail as possible by Dunbar et al. [114] and by Finlay [5]. Postnozzle evaporation quickly reduces droplet sizes, while aerodynamic drag rapidly decreases velocities. Ideally, these processes occur over a very short period of time, leaving behind a cloud of residual drug particles entrained in the patient's inspiratory airflow; however, in practice, the ballistic initial speeds of pMDI droplets lead to high deposition in the mouth and throat, thereby limiting lung deposition (e.g., see [115–118]).

A second issue that can reduce the efficiency of delivery from pMDIs is improper coordination between device actuation and patient inhalation. Difficulties with coordination are often reported anecdotally when pMDIs are used by children or seniors. Breath-actuated pMDIs, designed to release a metered dose at a specific point in the patient's inhalation maneuver, have been developed to overcome coordination problems [119, 120]. Another solution is to use add-on spacer or

holding-chamber devices, which fit between the pMDI mouthpiece and the patient. After the pMDI is actuated into a spacer, the patient may inhale the aerosol in one or more breaths. Spacers also serve the purpose of providing room (and therefore time) for pMDI droplets to evaporate and decelerate prior to reaching the patient, thereby reducing deposition in the mouth and throat [121, 122]. This reduction in mouth–throat deposition is often associated with deposition in the spacer itself; therefore, lung deposition does not necessarily increase when spacers are used with pMDIs. However, because deposition in plastic spacers often occurs due to electrostatic attraction of particles to spacer walls, coating spacers with ionic detergents (to remove static charge) has been predicted in vitro to increase lung deposition compared to that predicted for uncoated spacers [29]. In addition, nonelectrostatic metal and polymer spacers have recently become available [123, 124].

As with any aerosol drug delivery device, the efficacy of a pMDI can be evaluated in terms of a final clinical outcome. For example, the efficacy of an inhaled bronchodilator may be determined from the change in a patient's forced expiratory volume ($FEV_1$) from the baseline level [125]. Such clinical outcomes are, of course, paramount to the patient, but they provide little insight for researchers and developers into their underlying causes, as regional deposition patterns can only be inferred (i.e., more drug might be presumed to have deposited in the lungs when the clinical effect is greater). Regional deposition patterns can be measured in vivo by labeling the inhaled aerosol with radionucleotides and then imaging the respiratory tract after delivery [126, 127], or by measurement of pharmacokinetic parameters such as the absorption of drug into the bloodstream [125]. However, it is often desirable, especially in the early stages of development, to estimate regional deposition patterns without expending the time and costs associated with in vivo studies. In these circumstances, the performance of a device in vivo can be predicted using the various particle sizing techniques and mathematical deposition models describes earlier in this chapter.

As mentioned above in the context of particle sizing (Section 3.4), the sizes and speeds of pMDI droplets close to the spray nozzle are very difficult to measure. Unfortunately, it is these same sizes and speeds that to a large extent determine the division of deposition between the extrathoracic airways and the lungs. As such, one approach to estimating lung deposition from pMDIs is to actuate the device into a physical mouth–throat model and then to size the aerosol that passes through it ([87], and references therein). For the aerosol passing through the physical model, regional deposition may be predicted from the measured particle size distribution using a mathematical deposition model. The fraction of aerosol depositing in the physical model is then added to the mouth–throat deposition predicted mathematically, the assumption being that deposition in a patient's mouth and throat due to the initially ballistic speeds of pMDI sprays (which is not accounted for in the mathematical model) is accurately represented by the deposition in the physical model. Clark and Borgström [87] describe the success various researchers have had in predicting in vivo data using such an approach.

### 4.2 Dry Powder Inhalers

Another class of inhaler in wide use is the dry powder inhaler (DPI). These devices contain drug and excipients in the form of a fine powder, which is delivered to a patient during inhalation. DPIs are as portable as pMDIs, and in many cases have been developed as direct alternatives to pMDIs for treatment of asthma and COPD. The design of DPIs varies a great deal from device to device. Descriptions of a number of commercially available DPIs may be found in Dunbar et al. [128] and in Borgström et al. [129].

In general, the function of a DPI is to disperse a metered dose of powder into a patient's inspiratory airflow. This involves both fluidization of the powder from its bed and deaggregation of particle agglomerates. Normally, respirable size particles, with diameters on the order of a few microns, are manufactured by milling or spray drying. These particles readily adhere to solid surfaces, including device walls and neighboring particles, due to short-range intermolecular attractions (van der Waals forces). For respirable particle sizes, the aerodynamic forces associated with typical inhalation flow rates cannot overcome particle adhesion [5], so that powder dispersion is difficult to achieve. A solution to this problem is to add larger carrier particles, often lactose, to the powder formulation. The smaller drug particles adhere to the surface of the carriers to form agglomerate particles. Alternatively, small drug particles may be tumbled together to form a larger, agglomerate particle without the addition of excipient carriers. Agglomerate particles are typically formed with diameters ranging from 50 to 150 μm [129], so that the aerodynamic lift forces acting on them during inhalation are sufficient for fluidization [5]. A challenge for the formulator is to design powders for which the adhesion forces that hold agglomerate particles together during fluidization are sufficiently small that they can be overcome once the powder is entrained in the air, so as to return drug particles to respirable sizes. Several approaches can be taken to enhance deaggregation of airborne agglomerates, including generation of turbulence, and

**Figure 12** Illustration of powder formulation, fluidization, and deaggregation for a dry powder inhaler (DPI).

impaction onto grid or mesh surfaces. Figure 12 provides a schematic diagram of the formulation, fluidization, and deaggregation of DPI powders.

As reviewed by Chan [130], a number of approaches have been taken to improve powder dispersion in DPIs. One of these is to fabricate powders consisting of large, porous particles, so as to enhance the aerodynamic lift and drag forces acting on particles while maintaining small enough particle mass to avoid inertial impaction in the upper airways [131]. Another approach is to include a spinning impeller in the DPI to assist deaggregation [132], while still another relies on compressed air. Protection of DPI formulations containing hydrophilic particles from ambient humidity will also aid powder dispersion, as capillary condensation can increase particle–particle and particle–wall adhesions for such formulations [5, 133].

Cascade impactors are commonly used to size DPI aerosols. Chemical assay of impactor plates allows for the mass distribution of drug to be distinguished from that of excipient, carrier particles. In many cases, a similar experimental approach is used for DPIs as for pMDIs, where the aerosol is delivered to the cascade impactor through a physical mouth–throat model. However, for DPIs, the emitted particle size distribution can be strongly dependent on inhalation flow rate, as this flow rate influences powder fluidization and deaggregation; therefore, ideally, the flow rate through the impactor should match the flow rate at which the dose is expected to be delivered to patients [134]. As the dose may be emitted at different flow rates due to intersubject and intrasubejct variability in inhalation maneuver, it is useful to evaluate the variability of a DPI over a range of flow rates. The pressure drop, or resistance to flow, across a DPI is also an important parameter. High-resistance inhalers limit the range of flow rates that can be achieved by patients, thereby reducing variability in dosing; however, some patients may have difficulty providing a sufficient inspiratory effort to overcome the resistance in the device.

In estimating mouth–throat and lung deposition from DPI size distribution data, it is necessary to account for jetlike effects that can occur for small-diameter mouthpieces [41–44]. Such effects enhance deposition in the oral cavity, leading to higher overall mouth–throat deposition than would be predicted using correlations developed for mouthpieces of larger diameter, for example, those by Stahlhofen et al. [7] and Rudolf et al. [38]. DeHaan and Finlay [45] presented a correlation that was used to predict mouth-throat deposition for a variety of DPIs by accounting for mouthpiece effects. Reasonably good agreement with in vivo data available in the archival literature was reported [45].

### 4.3 Aqueous Aerosols

Many compounds can be dissolved, or suspended colloidally, in water. One of the oldest and simplest methods

used to generate medicinal aerosols for inhalation is to atomize these solutions and suspensions into fine droplets. Indeed, numerous inhalation drug delivery systems currently in use create aerosols from aqueous formulations. While the jet nebulizer has found wide use for decades, many of new devices have only recently been introduced, many of which have been developed with the goal of overcoming limitations traditionally associated with nebulizers.

***Jet Nebulizers*** A jet nebulizer produces aerosol droplets by passing a flow of pressurized air over a liquid surface. Unlike pMDIs and DPIs, which deliver metered doses in a single inhalation, nebulizers are designed to operate during tidal breathing, over several minutes. In addition, jet nebulizers rely on an external source of pressurized air to drive aerosol production. As a result, jet nebulizers are normally less portable than pMDIs and DPIs. Even so, for many applications, and in many geographic locations, nebulizers remain standard for drug delivery to the lungs.

Though the construction of the device can vary, a basic jet nebulizer design is shown schematically in Figure 13. Air supplied by a compressor, or from a wall source, is accelerated to high speed through a nozzle. At the nozzle exit the pressure is lower than that in the liquid reservoir, thus liquid is drawn up through a feed tube toward the high-speed air. This interface between liquid and air constitutes the region of primary droplet production. Different explanations have been proposed to describe the instability of the interface that coincides with the formation of primary droplets; however, it is likely the case that this instability results from the discontinuity in viscosity between air and liquid across the interface [5]. The large droplets produced at the interface are directed toward a primary baffle, where they splash and produce smaller, respirable size droplets. These droplets then flow around secondary baffles, which filter out any remaining large droplets, and exit the nebulizer through a mouthpiece.

**Figure 13** Schematic diagram of a typical vented jet nebulizer.

An important parameter in assessing nebulizer performance is the nebulization efficiency, that is, the fraction of the nominal dose put in the nebulizer that is delivered to the patient. The nebulization efficiency is highly dependent on the design of the device, particularly on its ability to recycle droplets collected on the secondary baffles and nebulizer walls back into the liquid reservoir, to minimize residual liquid left in the reservoir after nebulization, and to limit aerosol losses during exhalation. Typically, the supply of pressurized air to the nebulizer is smaller than the patient's inhalation flow rate, so that additional ambient air is inhaled. If this additional air is drawn through the nebulizer, as in Figure 13, the nebulizer is referred to as a vented, breath-enhanced, or active venturi, nebulizer. One-way inhalation and exhalation valves are employed to limit the amount of aerosol that escapes the nebulizer during exhalation. If, instead, ambient air is mixed with the nebulizer output at the mouthpiece, and no valves are employed, the device is referred to as an unvented nebulizer. In general, with other factors being equal, unvented nebulizers are less efficient than vented nebulizers, as more aerosol is wasted during exhalation. For young children, whose inhalation flow rates are smaller than the rate at which pressurized air is supplied to the nebulizer, nebulization efficiency is reduced even further, as a fraction of the aerosol is also lost during inhalation.

Another parameter used to assess nebulizer performance is the output rate, defined as the amount of drug that is delivered over a given period of time. Low output rates can reduce patient compliance, as treatment times become longer. As a nebulizer is operated, the concentration of dissolved drug in the solvent will gradually increase as a result of solvent evaporation [135]. This effect can lead to increases in drug output rate as nebulization progresses [136]. However, jet nebulizers also become cooler during operation as a result of solvent evaporation [135], and the increase in solvent viscosity with decreasing temperature can be expected to reduce the drug output rate [5]. Such an effect may limit increases in output rate owing to increased drug concentration in some cases, so that the output rate remains relatively constant (e.g., [137]).

Jet nebulizers produce aqueous droplets that can undergo hygroscopic size changes; therefore, care must

be taken in order to accurately determine droplet sizes. Different approaches to sizing volatile aerosols were discussed earlier in Section 3.4. Briefly, the aerosol should be sized in situ as close to the nebulizer mouthpiece as possible, or else hygroscopic size changes should be negligible during transit from the mouthpiece to a sizing device located at some position downstream. Clark [105] has described the use of laser diffraction instruments for sizing nebulizer aerosols, while Smaldone and Lesouef [138] have described sizing of nebulizer aerosols using low flow rate cascade impactors. In addition, Finlay et al. [103] combined size measurements for a range of jet nebulizers made using a phase Doppler particle analyzer with a mathematical deposition model to accurately estimate in vivo lung deposition data. In predicting respiratory tract deposition from measured droplet size distributions, it must be ensured that any effect of breathing pattern on aerosol production, as occurs for some vented nebulizers [103], is accurately captured in the experimental setup.

Quite recently, a group of "smart nebulizers" were developed [139], with the aim of improving nebulization efficiency and targeting of inhaled aerosols. Many of these devices only produce aerosol during patient inhalation and, thereby, minimize losses during exhalation [140, 141]. Such devices are classified as breath-actuated nebulizers. Another device used in combination with conventional jet nebulizers aims to optimize aerosol deposition in prescribed lung regions by combining breath-actuated nebulization with control of patient inhalation maneuvers [140]. This latter type of delivery system has promising potential for tailoring aerosol drug delivery to individual patients.

***New Aqueous Aerosol Generators*** The traditional jet nebulizer is inherently inefficient given that a large fraction of its dose is wasted during exhalation. In addition, treatment times for jet nebulizers are much longer than those for single-breath inhalers such as pMDIs and DPIs. Not surprisingly, much work has been done in recent years toward improving existing nebulizer designs and in developing portable, single-breath aqueous aerosol generators to compete with pMDIs and DPIs. Many newer devices rely on mechanisms other than jet nebulization in order to produce aqueous aerosols. These include, but are not limited to, vibrating orifice-based nebulizers [142, 143], electrohydrodynamic aerosol generators [144], and devices that force liquid through machined nozzle systems or arrays to produce fine droplets [145, 146]. Some of these devices are capable of producing very high fine particle fractions in slow-moving aerosol clouds, for which extrathoracic deposition is much lower than that for most pMDIs and DPIs [147]. In addition, the relative ease of aqueous formulation is advantageous in developing delivery systems for new drug compounds. Reviews of new technologies for delivery of aqueous aerosols to the lungs are available in Dennis and Nerbrink [148] and in Lange and Finlay [149]. It is anticipated that these technologies will play a significant role in the future of aerosol drug delivery.

### 4.4 Condensation Aerosols

Delivery systems that form aerosols from condensation of vapors constitute another class of inhalers that has emerged fairly recently [150–152]. Liquid solutions of drug [152] or solid films of drug [150] can be rapidly heated to form vapors, which then condense upon cooling and mixing with ambient airflow to produce aerosols.

Though condensation aerosol generators have been used for several decades to produce test aerosols in laboratory settings [9, 153], adapting the technology to drug delivery presents two clear challenges. First, the heat required for vaporization can cause decomposition of the drug, reducing bioavailability and potentially producing harmful combustion products. Second, condensation often produces aerosol particles with submicron diameters [152], for which deposition in the lungs by gravitational sedimentation is less probable than for micron-sized particles. As a result, a significant fraction of the dose inhaled by patients would be expected to be exhaled, though this limitation would likely be balanced by reduced extrathoracic deposition compared to traditional single-breath inhalers.

Rabinowitz et al. [150] demonstrated that for a variety of drugs medically suited for systemic delivery through the lungs, thermal decomposition can largely be avoided by keeping the time period over which the drug is vaporized very short. Furthermore, aerosols consisting purely of drug were produced with MMADs between approximately 1 and 3 μm [150] suitable for deposition in the peripheral regions of the lungs. However, MMADs decreased with increasing flow rate of mixing air through the device [150], owing to dilution of the drug vapor prior to condensation, and the tested flow rates were lower than typical patient inhalation flow rates through single-breath inhalers. Consequently, further study is required to determine the size of particles delivered to patients.

Condensation-based delivery systems likely will not be suitable for all drugs, as some will undergo degradation due to heating. Given the small particle sizes that are produced, such devices appear to be particularly attractive for delivery to the peripheral regions of the lungs, with the intention that the dose be absorbed into the bloodstream for systemic action. Although

condensation-based systems are promising, further research will be required in order to optimize particle size distributions for maximum lung deposition, while minimizing losses upon exhalation.

## 5. CONCLUDING REMARKS

Inhaled pharmaceutical aerosols are already widely used for treatment of respiratory disease. As next-generation devices, designed for delivery of drugs through the lungs into the bloodstream, reach the market, aerosol drug delivery stands to transform the manner in which many patients take their medication. In order to maximize the therapeutic benefit to the patient, while minimizing the risks of side effects and variability in dosing, understanding the link between physical properties of pharmaceutical aerosols and outcomes measured in the clinic is crucial. In large part, the quality of an aerosol delivery device is determined by its ability to limit deposition of drug in the mouth and throat, while maintaining an adequate delivered dose to targeted regions of the lungs. Consequently, the ability to predict regional deposition patterns of inhaled pharmaceutical aerosols, gained through an understanding of the mechanics governing particle transport and deposition in the respiratory tract, has proven indispensable in the development and evaluation of aerosol drug delivery systems. In the future, progress toward targeting pharmaceutical aerosols to more localized regions within the lungs, and toward tailoring delivery systems to individual users, should expand the range of drugs delivered through the inhalation route.

# RESISTANCE TO ANTIPLATELET THERAPY

Paul A. Gurbel and Udaya S. Tantry
*Sinai Center for Thrombosis Research, Sinai Hospital of Baltimore, Baltimore, Maryland*

## 1 INTRODUCTION

Atherothrombotic complications are the primary causes of cardiovascular mortality and morbidity. The common underlying pathological basis for the development of catastrophic ischemic events during cardiovascular diseases is the occlusive platelet-rich thrombus generation at the site of plaque rupture. Occlusive thrombus development is also responsible for microembolization, which results in microvascular dysfunction following stroke and myocardial infarction. Platelets are not only central to these thrombotic processes ("platelet hypothesis") but also play important roles in atherosclerosis, coagulation, and inflammation (Fig. 1) [1–3]. Therefore, pharmacological agents that suppress platelet function have proven to be beneficial during the acute settings of acute coronary syndrome (ACS) and percutaneous coronary interventions (PCI) where superior platelet inhibition is desired and also during long-term treatment of coronary artery disease, ischemic stroke, and peripheral arterial disease [4]. Since platelets are activated by multiple redundant pathways, simultaneous inhibition of two important secondary agonist pathways [thromboxane A2 by inhibiting cyclooxygenase-1 by aspirin and adenosine 5′-diphosphate (ADP) pathway by inhibiting $P2Y_{12}$ receptor by clopidogrel] is desired. Clinical efficacy of the dual antiplatelet therapy has been demonstrated in large-scale clinical trials. In these clinical trials, a "one size fits all" approach has been adopted without evaluating the platelet response in the individual patient. However, subsequent ex vivo laboratory evaluation of individual antiplatelet response indicated a wide response variability where a substantial number of patients were not receiving the desired benefits with the prescribed dosing regimens. This phenomenon is described as "antiplatelet resistance or nonresponsiveness" [5]. Moreover, continued occurrence of recurrent ischemic events among selected patients with high on-treatment platelet reactivity or among patients exhibiting antiplatelet resistance again highlighted the importance of limitations of uniform dual antiplatelet treatment strategy. Currently, 25 million people in United States use aspirin as an antiplatelet agent to prevent cardiovascular events, whereas, between 1998 and 2004, use of clopidogrel has increased over 7 times whereas the use of clopidogrel with aspirin has increased 16 times in the United States [6]. The "nonresponsiveness or resistance" to antiplatelet therapy is becoming a major concern. Therefore, numerous scientific meetings and hundreds of clinical publications have been focused on this phenomenon. However, the mechanism of antiplatelet resistance, and treatment strategies to address these concerns are still unclear.

## 2 ROLE OF PLATELETS IN THROMBOTIC EVENTS

Platelets are the smallest blood cells released from megakaryocytes in bone marrow and circulate in blood as disk-shaped anucleate fragments without attaching to the normal vessel wall. They play an important role during normal hemostasis by forming clots at the site of vascular injury to prevent excessive blood loss. In the

**Figure 1** The platelet hypothesis: The Nidus of evil.

setting of pre-existing dysfunctional endothelium and atheroinflammatory conditions, platelet activation is a central process precipitating the development of occlusive thrombus [7]. Platelets are activated by various pathophysiological processes such as altered shear forces and released soluble agonists at the site of plaque rupture. Endothelial denudation following plaque rupture leads to the exposure of collagen and von Willebrand's factor (vWF) as well as the synthesis of small quantities of thrombin generated by exposed tissue factor. Binding of collagen, vWF, and thrombin (primary platelet activating factors) to specific receptors on the platelet leads to the release of major secondary agonists such as thromboxane (Tx) $A_2$ from membrane phospholipids through cyclooxygenase COX-1 activity and ADP from dense granule secretion. These secondary agonists by paracrine and autocrine mechanism are responsible for the amplification of platelet activation and sustained platelet aggregation. TxA2 binds to thromboxane receptors, whereas ADP binds to specific G-protein coupled purinergic receptors, $P2Y_{12}$ and $P2Y_1$, which result in sustained platelet aggregation. Though both $P2Y_1$ and $P2Y_{12}$ pathways are needed for stable thrombus generation, the $P2Y_{12}$ pathway is a major pathway through which the activation of platelets by various primary and secondary agents converges in the activation of glycoprotein (GP) IIb/IIIa receptors ("final common pathway") and subsequent stable platelet–platelet aggregation (homotypic aggregation) [7–10]. Activation of platelet by these agonists also leads to surface expression of the activation-dependent molecules, P-selectin and CD-40L. These activation-dependent molecules facilitate the binding of platelets to leukocytes and endothelium (heterotypic aggregation) to further enhance inflammation and thrombin generation. Both homotypic and heterotypic aggregation lead to the release of microparticles that are important in the thrombosis, inflammation, and atherosclerosis processes [7, 8].

## 3 RATIONALE FOR ANTIPLATELET THERAPY

Platelet activation and high platelet reactivity to agonists in acute coronary syndromes and following percutaneous intervention have been associated with stent thrombosis, restenosis, inflammation, myocardial infarction, and other ischemic events (Fig. 1). Platelet activation is also associated with diabetes, hypertension, and hyperlipidemia [9]. Increased expressions of platelet surface markers and heightened platelet reactivity as measured by light transmittance aggregometry (LTA) have been demonstrated in patients with ACS [9]. Recent studies indicate that elevated posttreatment platelet reactivity after PCI is a risk factor for the development of long-term ischemic complications, stent thrombosis, and periprocedural myocardial necrosis [11–15]. Through crosstalk with the coagulation system, platelets play a fundamental role in generating a hypercoagulable state, which has been demonstrated as an important risk factor for ischemic events following stenting [16]. Thus, on one hand, platelets play an important first line of defense in the development of clot to arrest bleeding during normal physiological hemostasis, while on the other hand during pathological processes

the uncontrolled activation and high reactivity may result in various severe ischemic complications that position the platelet as a "nidus of evil" [7]. In these settings, the rationale for antiplatelet therapy is to prevent the development of thrombus formation, to arrest the procoagulant activity and finally to promote the dissolution of thrombus. The determination of optimal inhibition is dependent on the degree of ischemic risk and is counterbalanced by the risk of bleeding.

The meta-analysis of randomized trials of antiplatelet therapy have demonstrated a reduction in myocardial infarction (MI), stroke, and death with antiplatelet therapy (aspirin or another oral antiplatelet agent) in patients at "high risk" of cardiovascular diseases. This meta-analysis further demonstrated that low-dose aspirin (75–150 mg/day) is an effective antiplatelet agent for long-term treatment, whereas a higher initial dose of 150–300 mg aspirin may be required in acute settings of MI, ischemic stroke, and unstable angina where complete inhibition of thromboxane-mediated platelet aggregation is desired [17]. Based on these data, indefinite oral aspirin therapy for the secondary prevention of cardiovascular events is recommended [18, 19]. Addition of clopidogrel to aspirin is associated with significantly lower serious vascular events in the antithrombotic trialists' collaboration meta-analysis. Based on the marginal superiority over aspirin and less frequent gastrointestinal bleeding observed in the CAPRIE (clopidogrel versus aspirin in patients at risk of ischemic events) trial, United States Food and Drug Administration (FDA) approved the use of 75 mg/day of clopidogrel for patients with a history of recent heart attack, stroke, or established peripheral arterial diseases [20]. Subsequent clinical trials have demonstrated significant clinical efficacy of adding clopidogrel to aspirin in preventing cardiovascular events especially in high-risk patients [21–23]. A recent meta-analysis of randomized clinical trials that compared addition of clopidogrel to aspirin to aspirin plus placebo for the treatment of coronary artery disease demonstrated a small reduction in all-cause mortality in patients with ST-elevation myocardial infarction (6.3 vs. 6.7%, $p = 0.023$) and a modest reduction in myocardial infarction (2.7 vs. 3.3%, $p < 0.001$) and stroke (1.6 vs. 1.3%, $p = 0.002$) in patients with cardiovascular disease [24].

## 4 RESISTANCE TO ANTIPLATELET DRUGS

Despite significant benefits and widespread use of dual antiplatelet treatment, the continued occurrence of adverse ischemic events remains a serious clinical problem [1]. The major limitation of these clinical trials with dual antiplatelet therapy was the implementation of one size fits all principle while treating the wide range of cardiovascular patients. However, recent pharmacodynamic studies, based on the ex vivo measurement of antiplatelet response aggregation, have revealed various limitations of aspirin and clopidogrel treatment. There was a wide response variability with a certain percentage of patients exhibiting very limited response or complete nonresponsiveness. Moreover, small translation research studies correlated this nonresponsiveness to the occurrence of recurrent ischemic events. Other terms used to describe this phenomenon include "resistance" and "hyporesponsiveness." The phenomenon of resistance may be due to a (a) *pharmacokinetic* mechanism where a reduced absorption or conversion to the active metabolite leads to inadequate availability of drug/active metabolite to sufficiently block the respective receptor pathways, (b) *pharmacodynamic* mechanism where decreased response of platelets to the drug is observed and is due to variability in platelet response secondary to increased turnover of platelets, increased responsiveness of platelets to certain agonists, genetic variability of receptors or intracellular signaling mechanism, or interactions with other drugs at the active site of the receptors, and (c) *treatment failure* where patients may suffer recurrent vascular events despite inhibition of the platelet activation pathways by antiplatelet therapy [5].

Multiple signaling pathways mediate platelet activation and the occurrence of thrombotic events. Thus, a treatment strategy directed against a single pathway cannot be expected to prevent the occurrence of all events, and treatment failure following single antiplatelet strategy alone is not sufficient evidence of drug resistance. "Resistance" or nonresponsiveness to an antiplatelet is provided by persistent activity of the specific target of the antiplatelet agent. Since the active metabolite of clopidogrel irreversibly inhibits the $P2Y_{12}$ receptor, evidence for nonresponsiveness to clopidogrel is provided by high posttreatment $P2Y_{12}$ reactivity. For aspirin, the identification of resistance would use a laboratory technique that detects residual activity of COX-1 [5, 11]. The so-called resistance to antiplatelet drugs will be more meaningful only when there is a well-established laboratory method to measure the biochemical phenomenon of resistance that has a strong relation to the occurrence of adverse clinical outcomes. Thus, a standardized laboratory method and well-established criteria to define resistance are still unclear [25].

## 5 CLOPIDOGREL RESISTANCE

Activation of platelet $P2Y_{12}$ receptor by ADP is predominantly responsible for GPIIb/IIIa activation and sustained platelet aggregation [7, 8] (Fig. 2). The latter

**Figure 2** $P2Y_{12}$- Pivotal Platelet Receptor.

concept is supported by: (1) demonstration of adverse ischemic events associated with high on-treatment ADP-induced platelet reactivity [11], (2) superior clinical outcomes with respect to ischemia observed in patients treated with the more potent $P2Y_{12}$ receptor blockers [26] (3) recent observation of clustering of adverse events in the initial 90 days after stopping clopidogrel among both medically treated and PCI-treated patients with ACS [27]. A detailed meta-analysis of clinical trials comparing clopidogrel with aspirin revealed that clopidogrel is comparatively superior to aspirin in reducing the odds of serious cardiovascular events, including stroke, MI, or vascular death in high-risk patients. Moreover, treatment with clopidogrel and aspirin is associated with superior clinical efficacy compared to aspirin alone [7]. Now dual antiplatelet therapy is a widely adopted treatment strategy and has created a huge market, which was in excess of U.S. $6 billion in 2006. Ticlopidine, the first thienopyridine antiplatelet agent, was found to be superior to aspirin in reducing thrombotic risks during different pathological conditions including peripheral arterial disease. However, neutropenia and other deleterious side effects associated with ticlopidine led to the development of a more potent second-generation thienopyridine, that is, clopidogrel, which was associated with fewer adverse effects [7]. However, subsequent laboratory investigations of clopidogrel responsiveness, based on the ex vivo measurement of ADP-induced platelet aggregation, revealed various limitations: (i) a delayed onset of pharmacodynamic response, (ii) a modest degree of mean platelet inhibition (~ 30–50%) following an a maintenance dose (MD) of 75 mg or a loading dose (LD) of 300 or 600 mg, (iii) wide response variability and unpredictable response with substantial percentage of patients exhibiting nonresponsiveness or resistance, (iv) the potential influence of drug–drug interactions especially with lipophilic statins (e.g., simvastatin, atorvastatin, and lovastatin), and (v) the recent demonstration of an association between clinical adverse events including stent thrombosis and clopidogrel nonresponsiveness.

## 6 PHARMACOKINETIC AND PHARMACODYNAMIC PROPERTIES

Clopidogrel is a prodrug and is rapidly absorbed from the intestine following oral administration. Approximately 85% of the drug is hydrolyzed to an inactive carboxylic acid metabolite (SR26334) by hepatic human carboxylesterase (HCE-1) [28]. The remaining 15% of clopidogrel is first converted to 2-oxo-clopidogrel and subsequently in a multistep pathway to an active thiol metabolite, R-130964 by hepatic cytochrome P450 isoenzymes CYP3A4 and 3A5 and to a smaller extent by CYP2B6, 1A2, 2C9 and 2C19 [29, 30]. The short-lived active metabolite permanently binds to the $P2Y_{12}$ receptor via a disulfide bridge between the reactive thiol group and two cysteine residues (Cys17 and Cys270) present in the extracellular domains of the $P2Y_{12}$ receptor [31]. The half-life of the platelet bound clopidogrel metabolite was found to be 11 days as demonstrated by radioligand studies.

**Figure 3** Definition of Antiplatelet Resistance.

The inactive metabolite is a predominant form present in the systemic circulation following oral administration and its elimination half-life is 8 h after single and repeated administration. The binding of ADP to the $P2Y_{12}$ receptor is permanently inhibited and also the ADP-induced platelet aggregation in a time and dose dependent fashion [4]. There was a linear relationship between clopidogrel dose, absorption, active metabolite generation, and platelet inhibition. Therefore, repeated administration of 75 mg daily dose of clopidogrel leads to a steady-state inhibition of 40–50% in 4–7 days, whereas a loading dose of 300 and 600 mg clopidogrel leads to 40–50% steady-state inhibition at 24 h and 50–60% inhibition at 4–6 h, respectively. Clopidogrel is excreted in urine (50%) and feces (46%) [4, 7]. A wide interindividual variability was observed in clopidogrel absorption and also its hepatic conversion to active metabolite generation [7] (Fig. 3).

Clopidogrel mainly inhibits ADP-induced platelet aggregation. Clopidogrel also inhibits collagen- and thrombin-induced aggregation; however, the inhibitory effect on collagen- and thrombin-induced aggregation can be overcome by increased concentrations of these agonists. These findings suggest that clopidogrel indirectly inhibits the effect of these agonists via the attenuation of ADP-mediated amplification of the platelet response. Clopidogrel does not have any effect on ADP binding to the $P2Y_1$ receptor or the platelet response to $P2Y_1$ activation, which induces shape change and intracellular $Ca^{2+}$ mobilization [32]. Clopidogrel has also been reported to attenuate platelet-leukocyte aggregate formation and the levels of C-reactive protein (CRP), P-selectin, and CD-40L, as well as the rate of thrombin formation [7].

## 7 LABORATORY EVALUATION OF CLOPIDOGREL RESPONSIVENESS

A standardized laboratory method that simulates the in vivo platelet response to antiplatelet therapy is still lacking. Since clopidogrel specifically inhibits one of two ADP receptors, ex vivo measurement of ADP-induced maximum platelet aggregation by LTA has been the most commonly used laboratory method to evaluate clopidogrel responsiveness and is considered the gold standard [7]. (Recently, it was suggested that since antiplatelet drugs (especially clopidogrel), induce platelet disaggregation, the response to clopidogrel would be better demonstrated by measuring late platelet aggregation at 6 min after stimulation with ADP rather than maximum aggregation [33]. However, recent study based on the evaluation of both maximum and final aggregation from 100 consecutive patients undergoing stenting and treated with clopidogrel, indicated that both measurements were equivalent in determining the prevalence of clopidogrel nonresponsiveness [34]. Flow cytometric measurements of the expression of activated GPIIb/IIIa receptor and P-selectin expression after ADP stimulation can also identify clopidogrel nonresponsiveness and correlated with measurements of maximum aggregation stimulated by ADP [13, 35]. In addition, measurements of ADP-induced platelet-fibrin clot strength by whole-blood thrombelastography and the VerifyNow $P2Y_{12}$ receptor assay using ADP as the agonist can also be used to measure clopidogrel responsiveness as point-of-care assays [16, 36]. The platelet function analyzer (PFA)-100 method using cartridges based on collagen-ADP and whole-blood

**Figure 5** Laboratory Measurements of Antiplatelet Responsiveness.

aggregometry are associated with inconsistent estimates of platelet reactivity to ADP. The phosphorylation state of vasodilator-stimulated phosphoprotein is a specific intracellular marker of residual $P2Y_{12}$ receptor reactivity in patients treated with clopidogrel and can be measured by flow cytometry. This technique is perhaps the most specific indicator of residual $P2Y_{12}$ activity in patients treated with a $P2Y_{12}$ inhibitor. However, the methodology is labor intensive and requires permeation of the platelet membrane and use of monoclonal antibodies specific for phospohrylated vasodilator-stimulated phosphoprotein [14, 34, 37] (Figs. 4 and 5).

## 8 CLOPIDOGREL RESPONSIVENESS AND TIME OF TREATMENT

Similar to other drugs, response variability and nonresponsiveness to clopidogrel has been demonstrated in patients following coronary stenting. In an early investigation from our center, 96 patients undergoing elective

**Figure 6** Clopidogrel Resistance: The Importance of Time and Dose. (Adapted from [35] and [38].)

**TABLE 1 Clopidogrel Resistance**

| Investigators | n | Patients | Clopidogrel Dose (mg Load) | Resistance |
|---|---|---|---|---|

| Total | 616 | | | 5–44% |

stenting were treated with a 300-mg clopidogrel loading dose in the catheterization laboratory followed by a 75-mg maintenance dose. ADP-induced platelet aggregation and activation-dependent platelet surface marker expression (P-selectin and activated GPIIb/IIIa) were assessed at baseline and serially for 30 days following stenting. Response variability to clopidogrel was demonstrated as measured by all markers, and a certain percentage of patients were found to have no demonstrable antiplatelet effect [35]. In the latter patients, the difference between pre- and posttreatment ADP-induced platelet aggregation was ≤10%. We defined these patients as clopidogrel "resistant" or "nonresponsive" to clopidogrel therapy. A subgroup of resistant patients exhibited platelet aggregation that was greater after stent implantation than at baseline despite clopidogrel therapy. These patients were defined as having heightened platelet reactivity to ADP.

In the latter study, 53–63% of patients were resistant to clopidogrel treatment at 2 h poststenting; ~ 30% were resistant at day 1 and day 5 poststenting; and 13–21% were resistant at day 30 poststenting [35] (Fig. 6). Therefore, clopidogrel "resistance" in this study appeared to be time dependent. Based on the results, it was hypothesized that the occurrence of clopidogrel resistance might be related to the inadequacy of a 300-mg loading dose to provide sufficient active metabolite generation to arrest platelet reactivity in selected patients, and that these resistant patients may be at particular risk for thrombotic complications, including periprocedural infarction and stent thrombosis [35].

Since this initial description, multiple investigators have confirmed the phenomenon of clopidogrel resistance [38–46]. The prevalence of clopidogrel nonresponsiveness has been reported at 5–44%. This wide variation in prevalence is primarily due to dosing and is less related to various definitions, laboratory methods, and the time at which blood samples were evaluated for responsiveness [38–46] (Table 1). As demonstrated in Table 1, the data are markedly concordant. The higher

resistance estimates are present following the 300-mg loading dose and the lower estimates occur after the 600-mg loading dose [38, 40]. Diabetic patients who were on long-term dual antiplatelet therapy had a higher number of clopidogrel nonresponders compared to nondiabetic patients in a recent study [47].

## 9 CLOPIDOGREL RESPONSIVENESS AND EFFECT OF DOSE

Subsequent investigations have unequivocally demonstrated that clopidogrel nonresponsiveness is dependent on dose. In the largest pharmacodynamic study comparing 300 and 600-mg clopidogrel loading doses, treatment with a 600-mg loading dose during elective PCI reduced clopidogrel nonresponsiveness to 8% compared to 28–32% after a 300-mg loading dose (Fig. 6). Moreover, the study demonstrated a narrower response profile following treatment with 600 mg compared to 300 mg clopidogrel [38]. Muller et al. also observed a time- and dose-dependent effect of clopidogrel in patients undergoing stenting [40]. A similar increased responsiveness was also observed in the Intracoronary Stenting and Antithrombotic Regimen: Choice between 3 High Oral Doses for Immediate Clopidogrel Effect (ISAR-CHOICE) study, where a ceiling effect of platelet inhibition was observed with a 600-mg clopidogrel loading dose, whereas a nonsignificant increase in platelet inhibition was observed with a 900-mg loading dose [48]. In addition, recent studies have demonstrated the comparatively better inhibition of ADP-induced platelet aggregation with both single 600-mg loading dose and repeated 150 mg clopidogrel daily [49–51].

## 10 RELATION OF CLOPIDOGREL NONRESPONSIVENESS TO ADVERSE CLINICAL EVENTS

Limited data are available to link clopidogrel nonresponsiveness to the occurrence of thrombotic events, including stent thrombosis and periprocedural adverse clinical events [13–16, 44, 46, 52–59] (Table 2). Matetzky et al. studied clopidogrel responsiveness in patients undergoing stenting for acute ST-elevation myocardial infarction and found that patients who exhibited the highest quartile of ADP-induced aggregation had a 40% probability for a recurrent cardiovascular event within 6 months [44]. In the PREPARE POST-STENTING (Platelet Reactivity in Patients and Recurrent Events POST-STENTING) study, patients suffering a recurrent ischemic event within 6 months of elective stenting had high poststent platelet reactivity to ADP compared to patients without ischemic events despite dual antiplatelet therapy [16]. In the CLEAR PLATELETS (Clopidogrel Loading with Eptifibatide to Arrest PLATELET Reactivity) and CLEAR PLATELETS Ib studies, a 600-mg clopidogrel loading dose used to treat patients undergoing elective stenting was associated with superior early platelet inhibition compared to a 300-mg loading dose, and this inhibition was accompanied by a decrease in release of myocardial necrosis and inflammation markers [13, 52]. Cuisset et al. demonstrated that patients with high posttreatment platelet reactivity had an increased risk of cardiovascular events. More importantly, these patients were resistant to both clopidogrel and aspirin treatment [53]. Similarly Lev et al. demonstrated that occurrence of

**TABLE 2 Studies Linking Clopidogrel Nonresponsiveness to Adverse Clinical Events**

MACE = major adverse cardiovascular events.

creatinine kinase–myocardial band after stenting was more frequent in patients exhibiting aspirin and clopidogrel resistance [46]. Finally, significantly higher recurrent ischemic events within 6 months of the procedure were observed in patients who were on chronic clopidogrel therapy undergoing elective coronary stenting and had higher preprocedure ADP-induced platelet aggregation [15]. All these findings strongly suggest that a high platelet reactivity despite currently recommended antiplatelet therapy is a risk factor for ischemia in patients undergoing PCI.

Based on the analysis of flow cytometric measurements of intracellular vasodilator-stimulated phosphoprotein (VASP) phosphorylation levels, a specific intracellular marker of clopidogrel-induced $P2Y_{12}$ receptor inhibition, nonresponsiveness to clopidogrel treatment has been suggested as a risk factor for the occurrence of stent thrombosis [14, 54]. In the recent CREST (Clopidogrel Effect on Platelet Reactivity in Patients with Stent Thrombosis) study, elevated levels of ADP-induced platelet aggregation, ADP-stimulated expression of active GPIIb/IIIa expression and the $P2Y_{12}$ reactivity ratio measured by VASP phosphorylation were observed in patients with stent thrombosis compared to patients without stent thrombosis, indicating inadequate inhibition of $P2Y_{12}$ receptor [14]. Other investigators have reported that high ex vivo shear-induced platelet aggregation or prevalence of clopidogrel resistance despite dual antiplatelet therapy may be a risk factor for stent thrombosis [55–57].

## 11 MECHANISM OF CLOPIDOGREL RESISTANCE

The mechanisms responsible for clopidogrel response variability and resistance are incompletely defined. Differences in intestinal absorption, hepatic conversion to the active metabolite through cytochrome 3A4 (CYP3A4) activity, and platelet receptor polymorphisms have been suggested [5]. Only up to 30–50% inhibition of ex vivo ADP-induced platelet aggregation was demonstrated following a repeated daily dose of 75 mg in normal volunteers or loading doses of 300 or 600 mg in patients undergoing PCI [13, 35, 38]. This level of inhibition indicated an incomplete $P2Y_{12}$ receptor blockade and suboptimal inhibition of ADP-induced platelet aggregation. The repeated demonstrations that a high loading dose of 600 mg clopidogrel is associated with increased inhibition of ex vivo ADP-induced platelet aggregation in patients undergoing PCI and a decreased prevalence of nonresponders supports insufficient active metabolite generation as a major factor in clopidogrel resistance [13, 38, 40, 48].

Recent studies involving the measurement of hepatic cytochrome (CYP) P450 activity suggest that individual variations in the activity of this enzyme play a major role. In a landmark investigation, Lau et al. demonstrated that pharmacologic stimulation of CYP3A4 activity by rifampin enhances the inhibitory effect of clopidogrel, whereas agents that compete with clopidogrel for CYP3A4 activity (e.g., erythromycin) attenuate the antiplatelet effect of clopidogrel [60]. In addition, cigarette smoking, possibly by the effect of nicotine as an inducer of CYP1A2 activity and St. Johns Wort, an inducer of CYP3A4, have also been associated with enhanced clopidogrel responsiveness [61, 62]. However, coadministration of lipophilic statins (that compete with clopidogrel for CYP3A4) such as atorvastatin or simvastatin have been shown to attenuate the platelet inhibitory effect of clopidogrel in pharmacodynamic studies [63].

Controversy abounds in the literature with respect to clopidogrel–lipid soluble statin interactions. The retrospective and prospective studies reporting no relation of statin use to clopidogrel effect may be explained by (1) the low doses of atorvastatin used in the studies and (2) under power of the sample size of the non-CYPP3A4-metabolized statins when compared to the CYPP3A4-metabolized statins to demonstrate statistical significance. There is evidence that this drug–drug interaction may indeed be associated with increased adverse cardiac events. Although not statistically significant because of sample size, Weinberger et al. reported 26% increased odds ratio for mortality in patients on clopidogrel for an acute coronary syndrome prescribed atorvastatin versus other statin therapies [64]. Although the lipophilic statin–clopidogrel interaction has not been definitively demonstrated in retrospective analyses of large-scale clinical trials, a trend toward a better clinical outcome in patients coadministered clopidogrel and non-CYP3A4-metabolized statins compared to lipophilic statins has been reported [65] (Fig. 3).

Additional information supporting the pivotal role of CYPP450 in generating the active metabolite of clopidogrel was demonstrated in a small study involving human volunteers where the effects of the CYP3A4 inhibitor, ketoconazole, on the pharmacokinetics and the ex vivo platelet inhibitory effects of prasugrel and clopidogrel were investigated. Prasugrel is also a thienopyridine that requires conversion to an active metabolite by a hepatic cytochrome. In this study, ketoconazole coadministration did not have any effect on prasugrel-active metabolite generation or prasugrel-induced platelet inhibition, whereas clopidogrel-induced platelet inhibition was reduced following a loading dose as well as after a maintenance dose [66]. The latter effect on clopidogrel-induced platelet inhibition was accompanied by lesser active metabolite generation. Similarly,

in another study, prasugrel treatment was associated with superior active metabolite generation and platelet inhibition together with a lower incidence of nonresponsiveness compared to clopidogrel treatment [67].

In recent studies, the influence of CYP3A5 and CYP2C19 isoenzymes on clopidogrel metabolic activation and responsiveness has been demonstrated [68, 69]. Suh et al. demonstrated higher clopidogrel responsiveness among subjects with the CYP3A5 expressor genotype than subjects with the nonexpressor genotype. Moreover, worse outcomes were seen in patients undergoing stent implantation with the nonexpressor genotype following treatment with clopidogrel than in patients with the CYP3A5 expressor genotype [68]. Similarly, Hulto et al. [69] and Brandt et al. [69a] independently demonstrated the influence of the CYP2C19 genotype on clopidogrel responsiveness in healthy volunteers. To further support the drug–drug interaction at the CYP2C19 level, in this issue Gilard et al. [70] demonstrated that coadministration of proton pump inhibitors (omeprazole) with clopidogrel in patients undergoing stenting was associated with significantly less platelet inhibition. They measured platelet inhibition by a $P2Y_{12}$ receptor-specific vasodilator-stimulated phosphoprotein phosphorylation (VASP-P) assay at 7 days posttreatment rather than widely used ADP-induced platelet aggregation measured at 24 h posttreatment. Since, proton pump inhibitors (PPIs) are also metabolized by CYP2C19, it was logical to study the influence of PPIs on clopidogrel-induced effect on platelets. In this study, authors reported 4.31 times more chances of being a clopidogrel bad responder when patients were treated with omeprazole in addition to clopidogrel than clopidogrel alone. This study gains significant clinical interest because possible combination therapy of PPIs coadministered with clopidogrel to attenuate gastrointestinal bleeding [70].

Suboptimal platelet response to clopidogrel may be due to an increased number of platelet $P2Y_{12}$ receptors, or polymorphism of platelet receptors. Genetic polymorphisms of platelet GPIIb/IIIa, GPIa/IIa, or $P2Y_{12}$ receptors have been reported to affect platelet function and may influence clopidogrel response variability [71–73]. Recently, it was reported that an increased percentage of patients with peripheral arterial disease have the $P2Y_{12}$ receptor H2 haplotype [72]. However, in another study, the relation of this haplotype to clopidogrel responsiveness could not be demonstrated [73]. Since the relation of genetic polymorphisms to clopidogrel responsiveness is inconclusive, further studies are required to establish a correlation between receptor polymorphisms and clopidogrel nonresponsiveness.

It has been shown that patients with diabetes exhibit platelet activation and increased reactivity to agonists. The heightened platelet reactivity may be related to the increased prevalence of nonresponders and occurrence of ischemic events reported in patients with diabetes [74, 75]. It has also been reported that patients with a high body mass index (BMI) exhibited a suboptimal platelet response with the standard 300-mg loading dose [76].

All of the above data strongly support the importance of insufficient metabolite generation secondary to limitations in the intestinal absorption, drug–drug interaction at CYP3A4, or genetic polymorphisms of CYP isoenzymes as the primary explanations for resistance rather than genetic polymorphisms of platelet receptors or intracellular signaling mechanisms. The latter mechanisms may be relevant in those patients who remain resistant and with high platelet reactivity to ADP even after high dosing strategies.

## 12 MANAGEMENT OF CLOPIDOGREL RESISTANCE

### 12.1 Higher Doses

In recent clinical studies of patients undergoing stenting, a 600-mg clopidogrel loading dose was associated with a higher level of platelet inhibition, lower mean posttreatment reactivity to ADP, and a lower incidence of nonresponsiveness when compared to a 300-mg dose. Moreover, a 600-mg clopidogrel loading dose was associated with a narrower response profile [38, 40]. Kastrati et al. found that patients achieved additional platelet inhibition when a 75-mg/day clopidogrel maintenance dose was followed by an additional 600-mg loading dose [77]. In the CLEAR PLATELETS study a 600-mg loading dose was associated with a superior pharmacodynamic antiplatelet profile compared to a 300-mg clopidogrel loading dose [13, 52]. In the recent ISAR-CHOICE study, there was a ceiling effect in unchanged clopidogrel and clopidogrel metabolite levels and platelet inhibition with the 600-mg loading dose, and no significant additional effect was seen with the 900-mg loading dose. Based on the pharmacokinetic profile of the free drug and metabolites the investigators concluded that intestinal absorption was the major factor explaining response variability [48]. Recent studies have demonstrated the comparatively better inhibition of ADP-induced platelet aggregation with both single 600-mg loading dose and repeated 150-mg daily clopidogrel [49–51].

Thus, higher loading doses may be considered for selected patients exhibiting high platelet reactivity to ADP. However, the superiority of a high-dose regimen in reducing ischemic events and the associated risk profile compared to a standard dose has yet to be established in large-scale clinical trials. Despite these limitations, the current American College of Cardiology

(ACC)/American Heart Association (AHA) guidelines for percutaneous coronary intervention (PCI) provide a class IIa recommendation that "a regimen of greater than 300 mg is reasonable to achieve higher levels of antiplatelet activity more rapidly [18, p. e277] ." Finally, the ACC/AHA guidelines provide a class IIb recommendation that "in patients in whom subacute thrombosis may be catastrophic or lethal . . . platelet aggregation studies may be considered and the dose of clopidogrel increased to 150 mg per day if less than 50% inhibition of platelet aggregation is demonstrated" [18, p. e277]. The latter guidelines however, do not specify the methodology that should be used to assess inhibition. Moreover, there are very limited clinical data to support the cutpoint of 50% inhibition [18, 38]. In the CLEAR PLATELETS study we observed periprocedural myocardial infarction only in those patients with 5 μ*M* ADP-induced aggregation >50% [13]. In the CREST study the cutpoint for stent thrombosis was 20 μ*M* ADP-induced aggregation >40% [14].

### 12.2 New $P2Y_{12}$ Receptor Antagonists

New $P2Y_{12}$ receptor antagonists are currently undergoing investigation. AZD 6140 (Astra-Zeneca) and cangrelor (Medicines Company) are reversible, direct, and potent inhibitors of the $P2Y_{12}$ receptor [78–80]. AZD 6140 is an oral inhibitor whereas cangrelor is administered parentarally. Both of these agents exhibit more consistent and greater platelet inhibition compared to clopidogrel. The short onset and offset of action make these agents appealing adjunctive antiplatelet agents during PCI when maximum and rapid platelet inhibition of ADP-induced aggregation is desired [78–80]. Prasugrel is an irreversible inhibitor of $P2Y_{12}$ and, similar to clopidogrel, is a prodrug that requires metabolic activation [81–83]. In the JUMBO-TIMI-26 trial, prasugrel treatment was associated with a similar primary endpoint of significant bleeding compared to standard clopidogrel regimen (1.7 vs. 1.2), and the bleeding events were the same for all doses of prasugrel [81]. The pharmacodynamic profile of prasugrel is superior to clopidogrel and is associated with lesser incidences of nonresponsiveness, however, it is associated with increased bleeding events [82, 83]. All three of the above agents will undergo study in phase III clinical trials. Prasugrel is currently being compared to clopidogrel in an ACS trial in patients undergoing PCI.

## CONCLUSIONS

Clopidogrel use has increased over the last few years following its effectiveness together with aspirin in significantly reducing adverse events in large-scale clinical trials. At the same time, based on the laboratory evaluation of platelet response, wide response variability and nonresponsiveness in selected patients are also present. In the recent small studies, heightened platelet reactivity or clopidogrel nonresponsiveness in patients who were on clopidogrel treatment is associated with adverse thrombotic events including stent thrombosis. The primary reason is attributed to the suboptimal generation of active metabolite secondary to limitation in intestinal absorption, and drug-drug interaction at CYP3A4 and genetic polymorphism of hepatic cytochrome P450 isoenzymes. Use of higher loading or maintenance doses of clopidogrel or new and more potent $P2Y_{12}$ receptor blockers are potential alternative strategies. In addition, the treatment of dual antiplatelet therapies may be confined to the pharmacologic management of patients at high risk for arterial thrombotic events but not as a primary prevention strategy or as an alternative to anticoagulants.

## 13 ASPIRIN RESISTANCE

Aspirin (acetyl salicylic acid) was synthesized by Felix Hoffman in 1897 at the Bayer Pharmacological research Laboratories as a palatable alternative to widely used bitter taste painkiller salicylic acid. Sir John Vane in 1971, discovered the aspirin's antithrombotic potential [84]. Since then, it is consider as a wonder drug and is the most economical and effective antiplatelet drug prescribed for the treatment of cardiovascular and cerebrovascular diseases. The extensive analysis of primary and secondary clinical trials have indicated that aspirin treatment is associated with a 20–40% reduction in cardiovascular adverse events [17]. Based on the results of primary and secondary prevention trials, the U.S. Preventive Services Task Force (USPSTF) recommends that low-dose aspirin (75 mg/day) should be administered in patients whose 5-year risk of a first cardiovascular (CV) event is ≥3% and whose 10-year risk is ≥6%. The American Heart Association (AHA) recommends that 75–160 mg/day be administered to patients whose 10-year risk of a first CV event is ≥10%. Overall, the benefits of low-dose aspirin therapy for prevention of MI outweigh the risks of gastrointestinal and intracerebral bleeding in the latter risk groups [85]. A higher dose of aspirin may be also required during the conditions of high platelet turnover such a coronary bypass surgery. Since aspirin is ~150-fold more potent in inhibiting platelet COX-1 (antithrombotic effect) than COX-2 present in endothelial and other cells (anti-inflammatory effect), it is more effective as an antithrombotic agent at a 75–325 mg per day dose [4]. Despite these benefits, it has been reported that only slightly more than half of eligible patients receive the proper aspirin treatment.

Implementation of appropriate and widespread use of aspirin should be the focus of future primary and secondary prevention trials. Finally, whenever rapid and complete inhibition of thromboxane-$A_2$- induced platelet aggregation is desired, such as in the setting of acute MI, unstable angina, or PCI, a 150- to 325-mg aspirin loading dose is favored [18].

### 13.1 Pharmacokinetics and Pharmacodynamics

Aspirin is readily absorbed in the upper gastrointestinal tract with enteric-coated aspirin requires a longer time to absorb. Peak plasma levels of aspirin were observed within 40 min and platelet inhibition and also prolongation can be observed within an hour. The bioavailability of aspirin is 50%. Aspirin is mainly metabolized by intestinal and liver HCE-2 to acetic acetyl moiety and salicylate moiety [28]. Aspirin has a half-life of 15 min whereas salicylate has a half-life of 3–6 h. Platelet inhibition was observed even before the appearance of aspirin in systemic circulation with low-dose controlled-release aspirin indicated that acetylation of the platelet COX-1 takes place in the portal or prehepatic circulation. Therefore, thromboxane-related platelet inhibition or thromboxane metabolite measurement in serum is considered as a surrogate measure of aspirin bioavailability rather than measurement of salicylate levels in the venous blood. The antiplatelet effect of aspirin is primarily due to irreversible acetylation of a serine residue (Ser530) in COX-1 in platelets, which prevents the binding of arachidonic acid to the catalytic site. Subsequent generation of $TxA_2$ and $TxA_2$-induced platelet aggregation are inhibited for the life of platelets. Since life span of platelets in circulation is 10 days, it takes 8–10 days to achieve pretreatment level of platelet aggregation.

It was also suggested that normal hemostasis may be achieved with as little of 20% of the platelet having normal COX-1 activity and thromboxane synthesis. In this line, it was demonstrated that more than 95% inhibition of thromboxane synthesis is required to observe any clinical efficacy of aspirin treatment [4].

### 13.2 Laboratory Evaluation of Aspirin Resistance (Figure 5)

A reliable and specific laboratory method to identify aspirin resistance has not yet been uniformly accepted by investigators. Aspirin resistance has been regarded as the failure of aspirin to inhibit COX-1, the failure of aspirin to inhibit platelet function after stimulation by various agonists ("biochemical aspirin resistance"), or the failure to protect from cardiovascular events ("clinical aspirin resistance" or more specifically "treatment failure"). Based on different ex vivo methods and criteria to define aspirin resistance, various studies have reported a wide variability in the occurrence of aspirin resistance (<1–55%) [86–97] (Table 3). Laboratory methods including point-of-care methods using agonists such as ADP-, epinephrine-, or collagen-induced platelet aggregation do not solely indicate COX-1 activity and thus are fundamentally flawed in specifically measuring the platelet response to aspirin (Fig. 5). More specific methods that indicate residual COX-1 activity include arachidonic-acid-induced platelet aggregation and, more precisely, the measurement of the stable metabolite of $TxA_2$ in serum during aspirin therapy. Measurement of urinary thromboxane metabolite levels may not be indicative of platelet COX-1 inhibition exclusively.

### 13.3 Aspirin Resistance Is Assay Specific

Platelet aspirin resistance was found to be uncommon in complaint patients treated with high-dose aspirin (325 mg per day) when measured by cyclooxygenase-1 (COX-1) specific assays such as using arachidonic acid (AA)-induced light transmittance aggregometry (LTA) and thrombelastography [96]. In another study of patients with a history of myocardial infarction, 9% of patients were found to be noncompliant with aspirin therapy and only one patient was resistant to 325 mg aspirin therapy as measured by AA-induced LTA [97]. In a recent prospective, randomized, double-blind, double crossover investigation studying aspirin dosing using multiple COX-1 specific and nonspecific assays in patients with stable coronary artery disease ($n = 120$), it was found that aspirin resistance was rare (1–6%) using COX-1-specific methods (AA-induced LTA, VerifyNow Aspirin assay with AA cartridges, and AA-induced aggregation measured by thromelastography [TEG]) at all doses of aspirin compared to COX-1 nonspecific methods (1–27%). Moreover, a dose-dependent platelet response to aspirin treatment was observed using methods where collagen was used as an agonist such as collagen-induced LTA and PFA-100. The latter occurred in the presence of near complete inhibition of COX-1 enzyme activity as measured by AA-induced platelet aggregation, indicating that aspirin may have non-COX-1-mediated dose-dependent effects in platelets [98]. More importantly, these dose-dependent effects were more pronounced in patients with diabetes where treatment with higher doses was found to be effective in inhibiting platelet function [99]. Similar results reporting a low prevalence of aspirin resistance using COX-1 specific assays have been reported [100]. At the same time, further studies have found a correlation between

adverse clinical events and aspirin resistance measured by PFA-100 [100–106] (Table 4). Thus, taken together, all of these studies indicate that noncompliance, various assessment methods, and underdosing may all be important factors responsible for the reported variability in aspirin resistance estimates in clinical studies.

It has also been demonstrated in recent studies that aspirin resistance may be associated with clopidogrel resistance. Moreover, aspirin-resistant patients have been shown to exhibit high platelet reactivity induced by various agonists such as collagen and ADP in addition to arachidonic acid [46, 107]. Therefore, aspirin resistance as measured in these studies may mark a

platelet reactivity phenotype indicative of high risk for ischemic events.

In addition to the mechanisms described above to explain mechanism of antiplatelet resistance, role of other cardiovascular risk factors that are known to augment platelet reactivity such as smoking, diabetes, hyperlipidemia and hyperglycemia, nonadhenrence to the therapy and concomitant use of other nonsteroidal anti-inflammatory drugs especially observed with aspirin may affect the antiplatelet responsiveness, prevalence of antiplatelet resistance, and finally adverse clinical outcome [4, 108, 109].

### 13.4 Variability of Aspirin Efficacy in Reducing Ischemic Events

The benefit of aspirin treatment may be dependent on the type of clinical setting. Although a repeated dose of 30 mg per day is reportedly sufficient to fully inhibit COX-1 in platelets, a 75- to 150-mg daily dose for long-term prevention and a 150- to 300-mg per day dose to provide rapid and complete inhibition in high-risk cardiovascular patients is recommended [4, 17, 110, 111]. However, even higher doses have been recommended for patients with cerebrovascular disease to prevent ischemic complications [4, 17]. The benefit of aspirin therapy is more pronounced (up to 25% reduction in mortality) in high-risk patients, especially patients with previous myocardial infarction [110]. A similar benefit was reported in the Antithrombotic Trialists' Collaboration (ATT) analysis, whereas the Physician's Health Study demonstrated a 44% reduction in the incidence of first MI [17, 111]. In patients with acute ischemic stroke or in patients undergoing coronary bypass graft surgery, the aspirin effect is less pronounced, whereas a marked risk reduction has been reported in patients with advanced coronary artery disease [112]. The role of aspirin in the prevention of atherothrombotic complications in women and patients with diabetes remains unclear [113–115].

These findings suggest that different activators (thrombin, collagen, ADP, and thromboxane) may influence platelet aggregation depending on the type of disease encountered. Thus, aspirin may be less effective in some diseases where activation of the platelet is not dependent on thromboxane synthesis. This observation may be relevant to the occurrence of ischemic events despite aspirin treatment that is otherwise described as clinical aspirin resistance.

### 13.5 Clinical Relevance of Aspirin Resistance (Table 4)

In an earlier study, Grotemeyer et al. found that patients exhibiting aspirin resistance as measured by elevated

platelet aggregates ratio had a 10-fold increase in the risk of recurrent vascular events as compared to aspirin-sensitive patients (44 vs. 4.4%, $p < 0.001$) [9]. Using whole-blood aggregometry to evaluate aspirin resistance, Mueller et al. found an 87% increase in the incidence of reocclusion in "aspirin-resistant" patients who underwent balloon angioplasty and were treated with 100 mg aspirin daily for 18 months [116]. Using a more COX-1 specific method measuring urinary thromboxane (Tx), metabolite levels among patients enrolled in Heart Outcomes Prevention Evaluation (HOPE) trial for aspirin responsiveness, Eikelboom et al. found that the risk of MI, stroke, or cardiovascular death was greater in the highest quartile of urinary $TxB_2$ levels. These data suggest that suboptimal inhibition of COX-1 or nonresponsiveness to aspirin therapy is a major cardiovascular risk factor [92]. Gum et al. found a 5% incidence of aspirin resistance based on the criteria of ≥20% AA-induced aggregation and ≥70% ADP-induced aggregation in patients with stable cardiovascular disease treated with 325 mg aspirin daily for up to 2.5 years. Aspirin resistance was associated with a significant increase in the composite endpoint of death, MI, or stroke [90, 91]. Chen et al., using the Accumetrics point-of-care device with cationic propyl gallate as the agonist, found that despite treatment with clopidogrel and heparin, aspirin resistance as defined by this assay was associated with ~2.9-fold increase in the occurrence of myonecrosis following PCI [94]. Recent studies correlated adverse clinical outcomes in patients treated with aspirin in selected patients who were exhibiting aspirin resistance as indicated by PFA-100 methods [101–104].

### 13.6 Therapeutic Intervention of Aspirin Resistance

Initial studies have suggested that inhibition of COX-1 by aspirin can reach saturable levels (>95% inhibition) with a 100-mg daily dose [117]. In a double-blind, double-crossover study of outpatients with stable coronary artery disease, we investigated the antiplatelet effects of 81, 162, and 325 mg daily aspirin [98]. The antiplatelet effects of aspirin were dose independent when assessed by methods that directly indicate COX-1 activity. A higher dose (>75–325 mg/day) is not clearly associated with an increased clinical benefit but rather may be accompanied by an elevated risk of bleeding [4, 17, 110, 111]. However, some investigators have suggested that higher dosages may be more clinically effective [118]. Recent studies have suggested that 325 mg aspirin per day may be associated with lesser aspirin nonresponsiveness as measured by COX-1 specific methods [96, 97]. Thus, a higher dose and strict compliance to therapy may effectively overcome the occurrence of aspirin resistance in selected patients.

## 14 CONCLUSIONS

Reports of high incidences of aspirin resistance may be due to laboratory measurements based on nonspecific methods that do not isolate the response of platelet COX-1 to aspirin or an inadequate dose in selected patients. Noncompliance may also be an important factor related to aspirin resistance. Clopidogrel nonresponsiveness is a consistent phenomenon observed in research studies conducted at multiple sites utilizing various $P2Y_{12}$ receptor-specific assays. Data from small studies support that patients with high ex vivo platelet reactivity to ADP during and after percutaneous intervention may be at greatest risk for subsequent ischemic events.

However, at this time there are no uniformly established methods to quantify ex vivo platelet reactivity after clopidogrel and aspirin treatment or the extent of platelet inhibition by clopidogrel and aspirin. Therefore, specific treatment recommendations for patients exhibiting high platelet reactivity during clopidogrel or aspirin therapy or who have poor platelet inhibition by clopidogrel or aspirin are not established. A higher aspirin dose (≥ 325 mg/day) and strict compliance to therapy may overcome the occurrence of aspirin resistance in selected patients. A clopidogrel maintenance dose of 150 mg may be considered in patients exhibiting clopidogrel nonresponsiveness. In the near future new $P2Y_{12}$ receptor blockers will likely overcome the limitations of clopidogrel. The bleeding issue associated with prolonged dual antiplatelet therapy remains a major concern that has been highlighted by the recent results from the CHARISMA trial [119]. At this time, it is uncertain whether a threshold of platelet reactivity exists, beyond which ischemic event occurrence rises. Similarly, the threshold platelet reactivity for bleeding is also unknown.

In the future, routine measurement of platelet function in patients with cardiovascular disease may become the standard of care. The clinical utility of routine measurements of platelet function in patients treated with antiplatelet agents, akin to low-density lipoprotein (LDL) measurements in patients treated with statins, will be determined by definitive large-scale investigations addressing the link between insufficient platelet inhibition and cardiovascular thrombotic risk. Personalized antithrombotic treatment strategies may be determined by ex vivo measurements that identify critical pathways influencing thrombotic risk in the individual patient. Currently, treatment of patients who

exhibit heightened reactivity of these pathways with specific inhibitors is being investigated in small pilot trials.

# ANTIBIOTIC DEVELOPMENT

Robert L. Bettiker[1] and Jason C. Gallagher[2]

[2]*Temple University School of Pharmacy, Philadelphia, Pennsylvania*

## 1 BIRTH OF THE ANTIBIOTIC ERA

It is easily forgotten that antibiotics as we know them have only been available for about 70 years. Death from infection was a feared eventuality before quite recently, whereas now society almost seems to have the opposite problem—expecting easy cures from antibiotic therapy for nearly all infectious diseases. The early discoveries that were keystone events in antimicrobial development were due to combinations of luck, skill, ingenuity, and Nobel-Prize-winning research.

The antibiotic era was primed to begin after Alexander Fleming's famous observation in 1929 of a zone of inhibition around a *Penicillium notatum* mold on a Petri dish of staphylococci in his laboratory [1]. Fleming was wise enough to recognize that a natural substance was being secreted from the mold, and for the sake of convenience he named this substance *penicillin* to avoid calling it "mold broth filtrate," which is what his experiments began working with [1]. To Fleming, penicillin's greatest potential was to assist in the selection culturing of organisms that were penicillin resistant to prevent overgrowth of organisms such as streptococci and staphylococci on culture medium from samples taken in areas of mixed human flora. His paper only briefly mentioned its possible utility in treating infections, and the editor's first revision of the paper actually removed mention of this [1, 2].

The utility of penicillin as a therapeutic agent was first described by Chain et al. in 1940 [3]. By this point, sulfonamides had already been discovered and were being used therapeutically in the treatment of infections [4]. A group under the leadership of Gerhard Domagk experimented with a antimicrobial dye named prontosil that was eventually determined to be a prodrug of sulfanilamide [4]. Experiments in mice revealed prontosil's in vivo activity against streptococcal infections, and Domagk himself administered the drug successfully to his child when she developed a dangerous streptococcal infection. After the publication of Domagk's results, the discovery and development of many active sulfonamides followed with numerous compounds becoming commercially available [4]. Domagk won the Nobel Prize in Medicine in 1939 for his discovery of prontosil's antimicrobial effects, though he was prevented from receiving it until 1947 due to Hitler's policies [4, 5].

Chain et al. described penicillin's antimicrobial activity in a paper written in 1940 [3]. By this point, the active penicillin molecule had still not been isolated, but several researchers were working with active penicillin preparations in a similar manner to Fleming. Chain and co-workers were the first to investigate penicillin as a chemotherapeutic agent. They tested this by injecting groups of healthy mice with one of three bacteria: *Staphylococcus aureus*, *Streptococcus pyogenes*, or *Clostridium septicum* (formerly *C. septique*) [3]. Half of the mice were then given penicillin for different durations. Penicillin dramatically saved the lives of the treated mice, while all controls expired. This led to testing in human patients and the eventual availability of the refined drug for Allied soldiers in World War II. For their work in the discovery and development of

penicillin, Fleming and Chain and co-workers jointly received the Nobel Prize in Medicine in 1945 [2, 6].

The initial fortuitous discovery of penicillin and the development of the sulfonamides led to a massive expansion in the area of antimicrobial drug discovery. Another pioneer in this area was Salman Waksman at Rutgers University [7]. Waksman's laboratory sampled soil bacteria looking for naturally occurring "antibiotics," a phrase that he coined. After several failed compounds, the aminoglycoside streptomycin was discovered. Streptomycin was notable in that it was active against organisms that were resistant to both sulfonamides and penicillin. Most significantly, streptomycin has activity against *Mycobacterium tuberculum*. For developing the first agent active in the treatment of tuberculosis, Waksman was awarded the Nobel Prize in Medicine in 1952 [7].

These early advances paved the way for the development of further new antimicrobials, and many large pharmaceutical companies and university laboratories alike participated in their discovery and development [6]. As antimicrobials became utilized more frequently and bacteria were exposed to them, antibiotic resistance inevitably occurred. New antibiotics were needed to address the growing tide of resistant bacteria, and antibiotics that were active against the many organisms not treated by penicillin, sulfonamides, and streptomycin needed to be developed. Classes of antibiotics that have been developed include drugs active against cell-wall biosynthesis, bacterial protein synthesis, topoisomerases and bacterial deoxyribonucleic acid (DNA), folic acid synthesis, ribonucleic acid (RNA) polymerase, and several others. To examine how antibiotic development has progressed as bacteria have evolved and new needs have been met, we will examine the development of the penicillins.

### 1.1 Penicillin Development

Penicillin enjoyed tremendous use in the treatment of many infections after its potential was discovered, particularly in the treatment of wound infections caused by streptococci and staphylococci. Nevertheless, it was not long after it became widely used that clinicians began to notice that some infections that should have been cured with penicillin were no longer responding [6]. Initially, this was thought to be a problem of dosage, but eventually the production of penicillinases by different types of bacteria were discovered, most notably staphylococci [6, 8].

β-Lactamases are enzymes that destroy the β-lactam ring of penicillin molecules, rendering them inactive [6, 9]. The term penicillinase refers to a β-lactamase that is active against penicillins. These enzymes were uncommon initially, but, as staphylococci that could produce them gained a competitive advantage in a penicillin-filled world, they have proliferated. The vast majority of staphylococci are now penicillin resistant. To counteract the activity of penicillinases, researchers began chemical substitutions of the functional groups attached to the core of penicillin, 6-aminopenicillanic acid (6-APA) [6]. After rising to the challenge of producing 6-APA from penicillin, it was available as a nucleus for the substitution of multiple side chains to create many semisynthetic penicillins [6, 8]. Among the first of these semisynthetic penicillins was methicillin [6, 8]. Unlike penicillin, methicillin contains a large side chain that sterically inhibits penicillinase from reaching the β-lactam ring. Methicillin was the first of what would be known as the "antistaphylococcal penicillins," since resistance to penicillin was so common that it eventually became almost useless in staphylococcal infections [6, 8]. Methicillin was soon followed by other agents, including nafcillin and cloxacillin [6, 8]. Though methicillin was removed from the market due to concerns with nephrotoxicity from acute interstitial nephritis, its classmates remain in use in clinical practice.

Although the antistaphylococcal penicillins improved on the activity of penicillin against staphylococci, they did not improve on the poor gram-negative activity of penicillin. To address this gap, several classes of semisynthetic penicillins with a broader spectrum of activity were developed [6, 8]. The first of these were the aminopenicillins, beginning with ampicillin in 1961 [6, 8]. Aminopenicillins have a polar side chain that allows them to enter the porin channels in the outer membrane of some gram-negative bacteria, allowing for their activity. The introduction of ampicillin gave clinicians a drug that was more active against gram-negative organisms than penicillin [8]. This enhanced activity increased the ability to treat infections of the urinary and respiratory tract. However, ampicillin and other aminopenicillins were found to be inactive against some gram-negative bacilli, including *Pseudomonas aeruginosa* and the anaerobe *Bacteroides fragilis* [6, 8]. Also, they are as susceptible to penicillinases as penicillin and they are not active against penicillinase-producing staphylococci. As aminopencillins began to be used more frequently, resistance to them in previously susceptible organisms increased, and this was found to be due to penicillinase production in other organisms.

In 1967, carbenecillin was introduced to the antibiotic market. At the time, carbenecillin was unique in that it was the first penicillin with clinically useful activity against *P. aeruginosa*, a difficult-to-treat gram-negative bacillus [6, 8]. Carbenecillin and the other antipseudomonal penicillins also display activity against some Enterobacteraciae that were resistant to amino-

penicillins, such as the *Enterobacter* species. Though carbenecillin is active against *P. aeruginosa*, other antipseudomonal pencillins, such as ticarcillin and piperacillin, were found to have superior activity [8, 10]. However, the antipseudomonal penicillins are susceptible to many β-lactamases, including the penicillinases produced by staphylococci and many gram-negative bacilli. Hence, the search for even broader-spectrum penicillins continued.

Though improvements in the spectrum of activity of penicillin were made against staphylococci with the antistaphylococcal pencillins, and against gram-negative bacilli with the aminopenicillins and antipseudomonal pencillins, no single penicillin had been developed that encompassed all of these beneficial properties. The need for an expanded-spectrum penicillin that was stable to penicillinases was apparent. Scientists at Beecham Research Laboratories, who had taken part in the earlier development of the aminopenicillins and antipseudomonal penicillins, screened bacteria for the production of natural inhibitors of β-lactamase [9, 11]. They discovered that *Streptococcus clavuligerus* produced such a substance, which they named clavulanic acid [11]. Clavulanic acid structurally resembles a penicillin but has little antimicrobial activity. When given to a β-lactamase-producing organism, clavulanate irreversibly binds the β-lactamase [11]. If clavulanate and a β-lactam are given together to a β-lactamase-producing organism, the β-lactam will not be inactivated by the β-lactamase and is available to exert its pharmacologic effect on the microorganism, provided that it has intrinsic activity against it (such as with penicillinase-producing staphylococci and penicillins). The first penicillin–β-lactamase combination released was amoxicillin–clavulanate in 1981 [11]. Amoxicillin is an aminopenicillin closely related to ampicilllin, except for a hydroxyl substitution that allows for enhanced oral absorption [6, 8]. The co-formulation, named Augmentin, was significant in that it restored the intrinsic activity of amoxicillin against penicillinase-producing staphylococci as well as other penicillinase-producing organisms that had evolved resistance to aminopenicillins and some that intrinsically produce penicillinases, such as *B. fragilis*. The later combination of ticarcillin and clavulanate in one formulation rendered a broad-spectrum penicillin combination that was also active against *P. aeruginosa* [9].

Penicillins have played an important role in antimicrobial chemotherapy for decades, and they are an excellent example of how antimicrobial development progresses to follow the needs of patients. The relentless advance of bacterial resistance drives the continued need for new antimicrobials. Shortly after the introduction of methicillin in 1959, methicillin-resistant staphylococci were isolated [12, 13]. These methicillin-resistant organisms had evolved a change in the target enzyme of β-lactams, rendering all of them useless in the treatment of these pathogens [14]. Now methicillin-resistant *S. aureus* (MRSA) predominates in many U.S. hospitals and is increasing dramatically in the community setting [14]. Over 40 years after MRSA was first described, some anti-MRSA β-lactams are approaching the final stages of clinical development, of which the cephalosporin ceftaroline has been approved [15, 16]. It is inevitable that resistance to ceftaroline will emerge, and our pursuit of new antimicrobials will continue.

## 2 WHY DO WE NEED NEW ANTIBIOTICS?

Since the time of the first discovery of penicillin-resistant *S. aureus*, humans have been in a race with bacteria—developing effective antibiotics before the bacteria can become resistant to them. Antibiotic discovery and development is different from most other fields in two major ways. First, antibiotics must have differential effects on two very different organisms—the human host and the invading bacteria [17, 18]. The drug must harm the latter while passing harmlessly through the former. Enzymatic or metabolic targets must be selected such that the bacterial processes are poisoned, leaving a similar human process minimally impacted. Second, bacterial evolution far outpaces human evolution, and resistance development will change an antibiotic's effectiveness over time. The magic bullet penicillin that cured *S. aureus* endocarditis in the 1950s is rarely effective today [19]. This is not always the case in other fields: Although rarely used, the old "tried and true" propranolol is still available if we need it—not necessarily true with old antibiotics.

Approximately 2 million hospital-acquired infections occur annually in the United States [20, 21], causing some 90,000 deaths. The majority of these infections are caused by bacteria having at least some resistance [22]. The incidence of resistance in infections in the intensive care unit (ICU) caused by four of the most serious bacteria is on the rise (see Fig. 1). Clinicians in the United States, including the authors, are confronting *Acinetobacter* infections resistant to all standard antibiotics at an alarmingly increasing rate [23]. Many clinicians are forced to turn to the old drug colistin (polymyxin E)—once thought to be too toxic—to treat these infections [24, 25].

Resistant bacteria would not be the problem they are if we had antibiotics effective against them coming down the development pipeline. Such is not the case. Six new antibiotic classes were developed in the 1950s and 1960s, but only three new ones have since been approved

**Figure 1** Resistant strains spread rapidly [21]. This chart shows the increase in rates of resistance for three bacteria that are of concern to public health officials: methicillin-resistant *S. aureus* (MRSA), vancomycin-resistant enterococci (VRE), and fluoroquinolone-resistant *P. aeruginosa* (FQRP). These data were collected from hospital intensive care units that participate in the National Nosocomial Infections Surveillance System, a component of the Centers for Disease Control and Prevention (CDC). (Taken from: Infectious Disease Society of America, Bad Bugs, No Drugs: As antibiotic discovery stagnates, a public health crisis brews, July 2004, www.idsociety.org; accessed 17 May 2008.)

by the Food and Drug Administration (FDA): linezolid in 2000, daptomycin in 2003, and the topical retapamulin in 2007 [26]. All of these are agents against gram-positive bacteria only; no new novel drugs against gram-negatives have come to market in nearly half a century [27]. Ten other antibiotics have been approved since 1998, but these are modifications of existing drugs. For instance, tigecycline, a drug approved in 2005 for both gram-positive and gram-negative infections, is a derivative of the old drug minocycline [28]. Very real concerns exist that established resistance mechanisms will require little modification to inactivate these so-called "me-too" drugs.

Molecules can be combined into a single drug for increased efficacy or durability. Examples are numerous: ß-lactam/ß-lactamase inhibitors, trimethoprim-sulfamethoxazole, and quinupristin-dalfopristin [29]. Combinations of antibiotics marketed separately may be useful in treating resistant bacteria. For example, rifampin and colistin appear to help somewhat in multidrug-resistant *Acinetobacter* spp. infections [25], but this type of combination therapy has limited use clinically due to difficulties in evaluating in vitro susceptibilities to multiple simultaneous antibiotics.

How did we get to the twenty-first century with such a lack of effective antibiotics? Multiple problems exist along the entire drug discovery and development pathway. At the beginning of the pipeline, the source of new molecules to test has dropped to a trickle. Antibacterial screening programs are five times less likely to have a "hit" than one for mammalian cell targets [30]. As the oldest of living organisms, bacteria have had some 3 billion years of evolving in harsh environments and may be more resistant to molecular attack [19].

Once discovered, development costs for a new potential drug are enormous, some $800 million to $1.7 billion [21], and none but the largest pharmaceutical companies can invest in a compound that might never be approved. Smaller companies with promising molecules must entice a larger one to buy or license their drug. The exact pathway of development to approval is unclear as the FDA does not always have clear-cut guidelines on antibiotic approval [31]. The drug itself may be flawed for many reasons, for example, (1) toxicity to humans, (2) lack of bioavailablity pharmacokinetically, (3) inability to reach the molecular target due to difficulties in penetrating the bacterial cell wall or membrane, or to efflux pumps that remove the drug, or (4) lack of durability as the bacteria rapidly become resistant to the compound.

Incentives at the end of the pipeline are likewise feeble: Antibiotics are used for short durations, and some 250–500 persons need to be treated with an antibiotic to recoup the same return on investment as one person on a medication for a chronic disease [22, 31]. As resistance develops to a new drug—and it will—an antibiotic's effectiveness and earning potential will wane over time [32, 33]. Is it any wonder that, in 1990, half of all pharmaceutical companies in the United States and Japan cut back or cut out antibiotic research and development [21, 23]?

Bacterial resistance is such a public health problem that both the Infectious Diseases Society of America (IDSA) and the European Society of Clinical Microbiology and Infectious Diseases (ESCMID) have systematically expressed concern [21, 34, 35]. IDSA's "Bad bugs, no drugs" policy statement of 2004 listed legislative, FDA, and National Institute of Allergy and Infectious Diseases (NIAID) recommendations to address the problem (see Table 1). Response to the recommendations has been tepid.

## 3 ANTIMICROBIAL DISCOVERY

Two major aspects of locating a new chemical entity (NCE) with potential antibiotic properties are (1) a source of compounds to screen and (2) the screening process itself [36]. Pharmacokinetics and dynamics of the potential drug are two more areas of concern in antibiotic development. Although there are innumerable other steps in antibiotic development, the remainder of this chapter will focus on a few examples of these four areas.

Classically, sources of molecules include soil screening, fungal fermentation [36], and chemical compound

**TABLE 1 DSA's "Bad Bugs, No Drugs" Recommendations [21]**

| Congress | FDA | NAIAD |
|---|---|---|
| Establish a commission to prioritize antimicrobial discovery | Publish updated guidelines for antibiotic clinical trials | Aggressively encourage translational (bench to bedside) research |
| Restore patent time lost during FDA's review of priority antibiotics | Encourage imaginative clinical trial design that lead to insight of drug efficacy against resistant bacteria | Remove roadblocks to antibiotic R&D that exist in NIAID's structure, including unnecessary restrictions on companies' intellectual property rights |
| "Wild-Card" patent extension | Provide a clear definition of acceptable surrogate markers as endpoints for clinical trials | Develop collaborations with industry and the infectious diseases research community |
| Extend market exclusivity similar to pediatric and orphan drugs | Explore animal and in vitro infection models and surrogate markers to reduce the number of efficacy studies required for additional indications while maintaining safe and effective dose regimens | Sufficiently fund and rapidly launch NIAID's Drug Discovery and Mechanisms of Antimicrobial Resistance Study Section |
| Tax incentives for R&D of priority antibiotics | Grant priority antibiotics accelerated review status | Engage outside experts in research planning and ensure transparency in decision making |
| Measured liability protections | Explore with NIAID opportunities to streamline antibiotic drug development | Encourage research on topics related to conduct of clinical trials |
| Additional statutory flexibility at FDA regarding antibiotic approval | | Sponsor research into new rapid diagnostic tests for bacterial infections that, when available, could reduce the cost of clinical trials |
| Antitrust exemptions for certain company communications | | Encourage research on antibiotic use and resistance development |
| | | Fund placebo-controlled trials to evaluate the necessity of antibiotic therapy for selected diseases |
| | | Explore with FDA opportunities to streamline antibiotic drug development |

libraries. A possible new source is the use of genomics to look for potential antimicrobials among bacterial DNA [17]. Soil and fermentation sampling have the advantage of providing a vast number of molecules to screen simultaneously but often rediscover compounds already in use [36]. A large pharmaceutical company may have over 100,000 compounds available for an automated high-throughput screen (HTS). Genomic applications to antibiotic design may have the difficulty of interpreting what a particular piece of DNA does and has yet to pay off with a marketed antibiotic. If a "hit" occurs with a compound from any of the above sources, the molecule often must then be modified by medicinal chemists to decrease human toxicity, enhance bacterial killing, improve entry into the bacteria cell, prevent efflux out of the bacterial cell, or to broaden the spectrum of activity against bacteria.

Screens fall along two major classes: looking for growth inhibition from whole-cell bacteria and looking for inhibition of single molecular targets. A hybrid between source and screen is structural-based design [37], which uses the molecular structure of the bacterial target and computers to test various compounds for activity against it in silico [38]. Whole-cell screens have the advantage of only selecting products that have the ability to penetrate the bacterial cell wall and reach their metabolic target. Genomics is used for screens as well as bits of DNA are examined for potential targets, but suffer the same problem as when used as a source of molecules: What does a particular piece of DNA do and is it really applicable to the job at hand? The tried-and-true method—using soil samples as a molecular source in a whole-cell bacteria screen—worked well in the 1950s and 1960s when six new classes of antibiotics

were developed, but now no longer appears sufficient [19]. Novel ways of locating compounds and the use of more sensitive screens appear to be the next phase of antimicrobial drug discovery [22].

### 3.1 Sources of Compounds: Digging in Dirt

Bacteria themselves are the source of many of our current antibiotics [29]. One gram of soil can harbor some 1000 different species of bacteria [22], and many of them secrete substances toxic to their neighbors to get a survival edge. For example, chloramphenicol, clavulanic acid, erythromycin, gentamicin, rifampin, teicoplanin, tetracycline, and vancomycin all were isolated from soil bacteria [39]. All the easy ore, however, may have already been taken from this mine. Current soil screening laboratories often rediscover antibiotics already in use [17, 36], frustrating scientists looking for new compounds.

Many scientists are thinking of innovative ways to search the soil for potential agents. Bacteria are sought out in different locations, such as in lichen, on seaweed, in Alaskan soil, or in deep-sea mud. Advanced culture techniques are used to coax fastidious organisms to thrive in the test tube, since 99% of soil bacteria have not been cultured in vitro. Bacterial DNA can also be directly amplified from a soil sample, creating a genomics profile that is a potential blueprint for future antibiotics [17, 22].

### 3.2 Genomics: Stealing the Blueprints

The genomes of several bacteria have been mapped out. The science of genomics can use this or other information to sift through bacterial DNA looking for genes that may create molecules used against other bacteria [17]. Usually, scientists screen the DNA code by homology—looking for bits of DNA similar to the code of known antibiotics. Although no antibiotic in use has been discovered by this method, the science is still young and the hope is great.

## 4 THE SCREEN DOOR

The screen used to weed out useless compounds from potential great antibiotics may be the most important intellectual piece of a drug development program [18]. A screen too sensitive will swamp the development team with too many hits, yet a screen too specific will ignore compounds that, with some minor molecular tweaking, could have great potential.

### 4.1 Bacterial Whole-Cell Screens

The whole-cell screens—looking for compounds that inhibit growth of living bacteria—have the distinct advantage of finding only compounds that will reach their target (through the cell wall without being inactivated or pumped out) [19]. Whole-cell screens using resistant bacteria are likely to ignore known compounds already in use, allowing for focus on compounds useful against these problematic bacteria [22]. Nevertheless, such screens were not amenable to automated HTS, and molecular screens rose in popularity [17]. These in vitro screens often use a single metabolic reaction to test compounds against, often at an enormous rate. No antibiotics in use today arose from HTS [19]. HTS might not be amenable to antibiotic screening at all, as it is five times less likely to generate an antibiotic hit than when used as a screen for drugs for mammalian cells [30].

Merck has used a novel addition to the whole-cell screen to detect low levels of inhibitory compounds in soil or fermentation samples. Antisense RNA can lower levels of target enzymes in bacteria, making them more susceptible to minute levels of antibiotics that might have been previously missed in soil samples. Such efforts have yielded the potential drugs platensimycin and platencin, compounds that inhibit enzymes in the bacterial fatty acid synthase pathway. These molecules can kill MRSA in vitro and in the mouse model [22, 40–42]. These potential drugs were discovered by modifying the whole-cell screen in two fashions: (1) antisense DNA was used to weaken an enzyme system to make it more susceptible to minute levels of compounds and (2) the use of the fatty acid synthesis pathway as a screening target [42].

### 4.2 Targeting the Defenses: Inactivating Modes of Bacterial Resistance

Bacteria can become resistant to antibiotics via several pathways. They can degrade the drug, remove it from the inside of the cell via efflux pumps, modify the drug's target, reduce uptake of the drug, or overproduce the enzymes inhibited by the drug [29, 43–45]. One should not think of resistance as wholly a response to human use and overuse of antibiotics. Bacteria have been using them against each other for eons and already have countermeasures in place [39].

### 4.3 The ß-Lactamase Inhibitors

Targeting these countermeasures has worked spectacularly well for over 20 years in one specific area: the ß-lactamase inhibitors. As discussed above, bacterial

ß-lactamases cleave and inactivate penicillin and its derivatives. Inhibitors of these enzymes bind irreversibly and inactivate them. ß-Lactamase inhibitors are structurally closely related to the intended substrate of the enzyme—the ß-lactam antibiotic—possibly making it difficult for mutations to occur that will differentially ignore the inhibitor and still bind the substrate [46]. Perhaps this is why these drugs are still widely used and effective today.

Over 300 different ß-lactamases with different spectra of activity leading to more narrow or broader resistance have been described. They fall roughly into four categories: Class A, B, C, and D. Of the four classes, only class A is inhibited by clavulanic acid, sulbactam, and tazobactam (the commercially available ß-lactamase inhibitors) with any degree of consistency. New research into the field has yielded some prospects of inhibiting other classes of ß-lactamase inhibitors, but these currently are far from clinical trials [45].

### 4.4 The Efflux Pumps

Bacterial efflux systems pump harmful antibiotics and biocides out of the cytoplasm and periplasmic space and prevent them from reaching their targets [47, 48]. They were first recognized as mechanisms of antimicrobial resistance in 1980 [49]. Efflux pumps can protect bacteria by increasing their number in the membranes [50] or by mutations allowing them to pump out a broad array of antibiotics. The latter may confer multidrug resistance (MDR) status on a bacterium. Bacteria that produce antibiotics often use efflux pumps to render themselves immune to their own toxins [48]. Efflux pumps have contributed to resistance of many different antibiotics and biocides, including chloramphenacol [51, 52], metronidazole [53], quinolones [54, 55], macrolides [56], carbapenems [57, 58], streptogramins [59], tetracyclines [59, 60], linezolid [61], and chlorhexidine [62].

Poisoning bacterial efflux pumps appears to work in restoring antibiotic concentrations within the cell [63, 64] and successfully resensitizing bacteria in vitro to the antibiotic of concern [53, 58, 65]. Efflux pump inhibitors (EPIs) may also find a place in treatment of infections caused by relatively sensitive bacteria as a suppressor of resistance development [47, 66]. Few agents are approaching clinical trials, although the old antihypertensive drugs reserpine and verapamil [67], the H+/K+ adenosine triphosphatase (ATPase) pump inhibitors omeprazole and lansoprazole [68], and the two phenothiazines chlorpromazine and thioridazine appear to inhibit some efflux pumps [69, 70]. Unfortunately, drug levels required to inhibit efflux pumps are much higher than those normally used clinically [48].

Several screens have been employed to find EPIs that could prove useful in resensitizing resistant bacteria. Structural alterations of antibiotics to turn them into EPIs has met with some success in vitro but not clinically [71, 72]. A second system grows efflux-using bacteria with subinhibitory concentrations of antibiotics as a screen for EPIs that restore antibiotic sensitivity. Many compounds have been isolated via this method, but much work to further characterize them lies ahead.

One EPI coupled with an antibiotic has made it to human trials. The compound MP-601,205 is aerosolized and used to treat pulmonary exacerbations in cystic fibrosis patients along with ciprofloxacin. The company, Mpex Pharmaceuticals, has not revealed the structure or mode of action of its drug, which is in phase II trials [48].

EPIs may prove to be difficult to develop, as efflux pumps are widely diverse among the different bacteria. Antibiotic efflux may be mediated by more than one pump in a single organism [73–75]. Also, mutations do occur to render EPIs inactive [76], and an EPI may inhibit passage of only some antibiotics through a multidrug efflux pump and leave others unaffected [47]. Nevertheless, we await further information regarding this avenue of research that may extend the life span of both existing and future antibiotics.

### 4.5 Targeting Their Weapons: Inactivating Bacterial Virulence Factors

If a bacterium invades your body and does no damage, would you care? Virulence factors are an excellent target for use as antimicrobial screens, and there are an enormous number of them to shoot at. For instance, drugs that block the effects of edema factor from *Bacillus anthracis* could have a large impact on patient outcome [37, 77, 78]. Many bacteria can sense the presence of each other, and once they reach a critical mass—a quorum—various changes in virulence can occur. Interference with quorum sensing is another target [79]. Biofilms often occur when bacteria colonize artificial material, such as joint replacements or intravascular or urinary catheters, and render bacteria relatively resistant to current antimicrobials. Up to half of nosocomial infections in the United States involve indwelling devices, and molecules that inhibit biofilm formation could have a huge patient impact [80]. There are many other examples of virulence factors that could potentially be used as screens [23].

### 4.6 Structural-Based Design: The Source and Screen Hybrid

Structural-based design of drugs first became a possibility with the advent of X-ray crystallography, but it is

only recently that it has begun to pay off with medications. Several antiviral drugs, including some human immunodeficiency virus (HIV) protease inhibitors [81, 82] and the influenza neuraminidase inhibitor zanamavir [83] are examples. To date, no antibiotics have come from this method, but there are many prospects [37].

Structural-based design used X-ray crystallography structure of a known target—in the above cases, either HIV-1's protease or influenza's neuraminidase—to search for compounds with a potential fit in an active site. Each possible fit, or hit, was then used in silico or in vitro HTS of similar compounds to improve binding and inhibition. Combinatorial chemistry could be used to modify molecules based on their predicted structural interactions with the binding site [38].

Although there are many prospects, no antibacterial or antifungals have come to the clinics via this method. One difficulty lies in the difference between a compound's minimum inhibitory concentration (MIC) for the target in question versus the MIC for a whole bacterium. A molecule can poison a particular enzyme or metabolic process quite well in silico or in vitro, but if the bacteria block its entry, kick it out, or destroy it before it can reach the target, then it is quite useless [17]. Chemistry must alter the compound's structure to allow it to pass through the cell wall and membrane safely without being pumped out or destroyed [38].

Structural biology is thus another tool in drug design and development. It can help to narrow the range of compounds to try and even help to locate new targets on a large molecule, but every hit must still be vetted by the in vitro, in vivo, and, finally, clinical trials processes.

Nevertheless, advances in this field may make it a far more useful tool. Better protein crystallization, X-ray crystallography, and software make it easier to prepare compounds for examination, to view them with higher resolution, and to manipulate them more easily in silico [38]. Genomics can allow an entire bacterium's DNA to be examined at once to search for potential targets over a vast array of proteins [18, 23]. Prediction of protein structure from DNA sequences continues to improve, and homology from other known protein structures allow for prediction of function and of the level of criticalness for a bacterium [37].

The preceding examples are just a few of the potential sources and screens of antibiotics that can help clinicians in the fight against bacteria.

## 5 PHARMACOKINETICS

The pharmacokinetic considerations in antimicrobial therapy do not differ greatly from those of other drugs. Drug concentrations must always be considered at the site of the infection, and the clinician must remember that plasma concentrations are only a surrogate marker for concentrations at other sites in the body.

### 5.1 Absorption

The bioavailability of oral and intramuscular formulations of antibiotics must be considered when they are given through these routes of administration. High oral bioavailability with a potent antibiotic is particularly desirable since these drugs can be given easily on an outpatient basis. Nevertheless, this is not the case with many antibiotics currently on the market. For β-lactams in particular, very few agents available orally can achieve the high concentrations of their intravenous counterparts.

Transitioning patients with serious infections from intravenous to oral therapy is a common practice in the hospital. Transitions to oral therapy take several forms [84]. A transition to an equipotent oral drug, such as from an intravenous cephalosporin to an oral fluoroquinolone, can be considered a therapeutically equivalent switch [84]. These differ from step-down therapy, where the oral drug being used is less potent than the intravenous drug [84]. This can occur if the oral drug has a lower bioavailability or other inferior pharmacokinetic parameters to the intravenous one. An example of this would be transitioning a patient from intravenous ampicillin to oral ampicillin, where the lower absorption and decreased tolerance of the oral drug makes the therapy a step-down from the intravenous form. This may be acceptable if the infection has largely resolved, but clinicians need to be aware that a change is taking place [84]. Some antibiotics with very low bioavailability nonetheless have oral utility. Some infections within the alimentary canal are better treated with oral rather than intravenous antibiotics. The oral absorption of vancomycin is very low, but this allows for very high vancomycin concentrations in the gastrointestinal tract and the efficacious treatment of *Clostridium difficile*–associated disease. Oral ampicillin is preferable to intravenous ampicillin for gastroenteritis caused by *Salmonella* species.

### 5.2 Distribution

Distribution is probably the least understood pharmacokinetic variable for many clinicians when choosing antibiotic therapy. The ability of the antibiotic to achieve an adequate concentration at the site of infection must always be considered. The blood–brain barrier (BBB) is an effective obstruction to the penetration of many antibiotics into the central nervous system (CNS) [85]. When the BBB is inflamed, such as in meningitis, CNS

penetration is easier to achieve [85]. Some antibiotics are useful in treating CNS infections even though they can only penetrate the BBB when it is inflamed.

Abscesses are localized collections of microorganisms and leukocytes that are self-contained. In general, antibiotics do not penetrate abscesses and surgical procedures are often required. Organs that many antibiotics have difficulty penetrating include the eyes, prostate, and bones.

The distribution of antibiotics may be variable between patients. It may be limited by patient factors, such as poor circulation to peripheral tissues in diabetic patients. Certain patient populations have inherently larger volumes of distribution, such as burn patients and patients with cystic fibrosis. This is relatively insignificant for antibiotics with very large volumes of distribution, but significantly affects the utilization of some drugs, such as aminoglycosides. The pharmacokinetics of many antibiotics in obesity are not well characterized.

### 5.3 Metabolism

As a class, relatively few antibiotics undergo considerable hepatic metabolism. Of the agents that do, few require significant dosing adjustment in liver disease. Pharmacokinetic drug interactions with antibiotics are mainly due to effects on the cytochrome P450 system [86]. Induction or inhibition of these enzymes is common among agents in a few classes of antibiotics, including azole antifungals, rifamycins, macrolides, and ketolides [86].

Extra-hepatic metabolism occurs with some antibiotics, though not commonly to an appreciable extent. Imipenem, a carbapenem antibiotic, is degraded in the kidney by renal dihydropeptidase into a nephrotoxic metabolite [87]. To counter this reaction, imipenem is co-formulated with cilastatin, an agent that inhibits this enzyme and allows for greater in vivo imipenem concentrations without the development of the nephrotoxic metabolite [87]. Anidulafungin is an echinocandin antifungal that is not hepatically metabolized or renally eliminated, but slowly degrades to inactive products in plasma [88].

### 5.4 Excr\etion

Renal excretion is the predominant method of elimination for many, if not most, antibiotics. Variations in the rate of elimination between patients can lead to significant accumulation of active drugs, and doses often need to be adjusted to account for these differences. Careful phase I pharmacokinetic studies need to be performed to establish correct doses for further clinical study, particularly for drugs with dose-related toxicity. Imipenem, the carbapenem mentioned above, was originally given in higher doses than are currently used. After seizures were noted in some patients, further investigations led to more accurate dosing in patients with renal dysfunction, as it was determined that elevated concentrations of the drug were responsible for this adverse effect [89]. Seizures associated with imipenem are uncommon when it is dosed appropriately [89]. One therapeutic advantage of renally eliminated antibiotics is that they are often useful for the treatment of urinary tract infections.

Antibiotics may also be excreted through the biliary route. Many drugs eliminated this way have the advantage of not requiring dose adjustment in renal dysfunction, which is a much more prevalent problem than hepatic dysfunction. However, this can eliminate their therapeutic potential for the treatment of infections of the lower urinary tract, including the very common infection of cystitis. Moxifloxacin is a fluoroquinolone that, unlike other fluoroquinolones, is eliminated through the biliary tract [90]. It has not been studied formally for the treatment of urinary tract infections, but it is unlikely to reach concentrations high enough to be effective in the treatment of cystitis. This makes moxifloxacin easy to dose in patients with renal dysfunction but lowers its utility in treating cystitis, therefore missing an important target market. Some drugs have dual elimination routes, eliminated via both renal and hepatic excretion. Ceftriaxone is a third-generation cephalosporin that is eliminated this way [91]. One of the reasons for the popularity of ceftriaxone is that its dual elimination does not require adjustment in renal failure, allowing for ease in dosing. This is a potential advantage from the viewpoint of the prescriber, but not necessarily the pharmacy department since drugs that need to be renally adjusted are given in lower doses in patients with renal dysfunction, lowering direct drug costs. In addition to not needing dose adjustment in renal disease, ceftriaxone reaches concentrations in the kidney and bladder that are adequate for treating urinary tract infections [91].

## 6 PHARMACODYNAMICS

In addition to considering the pharmacokinetics of an antimicrobial agent, the pharmacodynamics need to be considered. Pharmacodynamics is the field of study that evaluates the effects of drugs at given concentrations on patients, diseases, and in the case of infectious diseases, on microorganisms [92, 93]. That is, where pharmacokinetics is the study of "what the body does to the drug," pharmacodynamics studies "what the drug does to the body."

The study of antimicrobial pharmacodynamics has expanded considerably in recent years. Earlier studies of infected patients established doses of antimicrobials for infections based on observed effects—when a drug was given at a certain dose, infections either were or were not cured. Advances in microbiology and pharmacodynamics have coincided, and the ability to monitor concentrations of drugs and relate them to their effects is what has given birth to the field of modern antimicrobial pharmacodynamics.

### 6.1 Bactericidal versus Bacteriostatic Effects

One primary pharmacodynamic effect of antimicrobials is whether a given antimicrobial exerts a bactericidal or bacteriostatic effect at commonly achieved concentrations in the body. Bactericidal (or fungicidal) drugs actively kill bacteria at achievable concentrations [93]. The concentration at which the number of bacteria in a sample is reduced by 99.9% is referred to as the *minimum bactericidal concentration* (MBC) [93]. Bactericidal drugs readily achieve these concentrations in vivo at the site of infection. This contrasts with bacteriostatic or fungistatic drugs, which inhibit bacterial or fungal growth [94]. These drugs rely on the function of the immune system to kill the bacteria, and for that reason are not preferred in disease states where the immune response in inadequate, such as in meningitis, febrile neutropenia, or endocarditis [95]. For most indications, however, bacteriostatic activity is adequate [95]. The lowest concentration at which bacterial growth is inhibited is called the *minimum inhibitory concentration* (MIC) [95]. All organism–drug combinations have both MICs and MBCs associated with them. For a drug to be active against a given organism in a given infection, it has to achieve concentrations above the MIC of the organism at the site of the infection. If a drug is bactericidal against an organism in an infection, it had to achieve concentrations above the MBC, which is always above the MIC [93, 95]. If the MBC and MIC are close, the drug is likely to be bactericidal. When MICs are relatively low and MBCs are relatively high, a drug is bacteriostatic. If the MIC for an organism is not achievable for a drug, then that drug will be inactive against that organism.

MICs are much more easily measured by microbiology labs than MBCs and are therefore the values used to guide pharmacotherapeutic decisions in clinical practice [95]. Hence, clinicians often rely on historical data to determine whether a drug is likely to be bactericidal against an organism, not patient-specific data. However, the ease in testing MICs makes susceptibility testing for most organisms relatively easy. Standards for the definition of "susceptible" are defined by regulatory agencies based on achievable drug concentrations. Microbiology labs compare the MICs of given clinical isolates to determine the likelihood of successful therapy by various antibiotics and report these to clinicians.

### 6.2 Concentration-Dependent and Time-Dependent Drugs

One of the most important pharmacodynamic considerations is the development and use of an antibiotic is to determine the type of activity the agent possesses [94]. *Concentration-dependent* drugs have antimicrobial therapy that is dependent on high concentrations in vivo relative to the MIC of the infecting organism [94]. Concentration-dependent drugs are maximized when maximum concentration to MIC ($C_{max}$:MIC) ratios are 10:1 or more [96]. This is achieved by giving high doses of the antibiotic, generally relatively infrequently. The dosing schedule is based on the rate of elimination of the drug ($K_e$) and the ability of the host (patient) to tolerate high concentrations of the antibiotic. Ideal $C_{max}$:MIC ratios may involve supratherapeutic concentrations that lead to undesirable effects in patients, though adverse effects are not necessarily concentration dependent.

Concentration-dependent drugs contrast with *time-dependent* drugs, which have activity that is best defined by the time that the drug concentration exceeds the MIC of the organism [94]. Time-dependent drugs are also called concentration-independent drugs since the concentration generally has minimal effect on efficacy as long as it remains above the MIC. The efficacy of time-dependent drugs is increased by maximizing the time that the concentration at the site of the infection is above the MIC (time > MIC) [92, 93]. High concentrations are not more effective than lower concentrations just above the MIC, at least not proportionally, though they may expose patients to higher incidences of unwanted adverse effects. The ideal method of administering a time-dependent drug is by continuous infusion, a regiment that is pharmacodynamically optimized but often impractical. To compensate for practicality, most time-dependent drugs are given frequently to imitate the effects of a continuous infusion. For many time-dependent antibiotics, the time > MIC needed for maximal efficacy is less than 100% [93, 97]. This varies for both each class of antimicrobials and the organisms that cause infection (see Fig. 2).

### 6.3 Postantibiotic Effects

The antimicrobial effect of some antibiotics extends beyond the time that the drug is present at the site of infection. The time that organism growth is inhibited

**Figure 2** Concentration versus time dependency [93]. Time–kill curves for *P. aeruginosa* ATCC (American Type Culture Collection) 27853 with exposure to tobramycin, ciprofloxacin, and ticarcillin at concentrations from one-fourth to 64 times the MIC.

despite drug concentrations below the MIC of the organism is referred to as the *postantibiotic effect* (PAE) [93]. During the PAE, the organisms are still recovering from the effects of the antibiotic exposure. PAEs may be concentration dependent, thus maximizing the dose of a drug may increase the PAE and allow for infrequent dosing, as with aminoglycosides [93, 96].

All antibacterials have a PAE against gram-positive bacteria, but PAEs against gram-negative organisms are less common [93]. PAEs measured in vitro are often less than in vivo PAEs due to the additional interactions of neutrophils and antimicrobial pharmacokinetics that do not exist in vitro [93]. Bacteria exhibiting the PAE after exposure to aminoglycosides and fluoroquinolones are more susceptible to destruction by leukocytes, thus prolonging the PAE in vivo [96, 98].

### 6.4 Examples of the Application of Antimicrobial Pharmacodynamics

***Aminoglycosides*** Aminoglycosides have been available since the discovery of streptomycin. The development and discovery of other aminoglycosides soon followed, and their broad-spectrum gram-negative activity and antipseudomonal nature led to much utilization of aminoglycosides for hospital-acquired infections. However, aminoglycosides have significant toxicities, most commonly dose-limiting nephrotoxicity [99]. Though aminoglycosides were known to be toxic above certain threshold trough concentrations and effective only if peak concentrations were reached in infected tissues, the ideal way of administering aminoglycosides was not known for many years.

These issues were improved upon by pharmacodynamic studies into both the toxicity and efficacy of aminoglycosides that followed their introduction years later. The uptake of aminoglycoside molecules into the nephrons in the kidney was found to be saturable [94]. Thus, once a threshold value of aminoglycoside exposure was reached within the nephron, greater concentrations had no effect. Also, aminoglycosides were found to be concentration-dependent drugs that were most efficacious with plasma concentrations 8–10 times greater than the MIC of the infecting organism (assuming adequate tissue penetration) [94, 99]. A dose-dependent postantibiotic effect was also noted with aminoglycosides [94, 99]. This led to a change in how aminoglycosides are dosed. Instead of multiple daily doses that lead to only moderately high peaks and somewhat low troughs, extended-interval dosing took advantage of the pharmacodynamics of the drugs. With extended-interval dosing, high doses of aminoglycoside are administred once a day or less [94, 99]. This maximizes the peak:MIC ratio and gives a trough concentration close to zero, allowing the kidney an aminoglycoside-free time period that seems to decrease nephrotoxicity [94, 99]. This dosing method has not become standardized and has not been studied in all patient populations, but it is common. Its efficacy and safety have been validated in multiple clinical trials and meta-analyses [94].

***Daptomycin*** Daptomycin is a cyclic lipopeptide antibiotic that is active against gram-positive cocci, including methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant enterococci, two types of

organisms for which limited therapeutic options exist. It was originially developed in the late 1980s and early 1990s by Eli Lilly and Company and was studied at a dose of 4 mg/kg twice daily [100]. However, during clinical trials, high rates of elevations of creatine phosphokinase were found, indicating that skeletal muscle toxicity was occurring that could possibly lead to the dangerous condition of rhabdomyolysis [100]. Further development of the drug was halted until Cubist Pharmacueticals purchased the rights to study and market daptomycin years later. As daptomycin was found to be concentration dependent, Cubist studied the drug with a once-daily administration dosing regimen and did not find the toxicity described in early studies [100]. It was concluded that the likelihood of skeletal muscle toxicity was related to the frequency of administration, and the drug was approved for a once-daily regimen.

***Extended-Infusion β-Lactams*** β-Lactams are the largest class of antimicrobial drugs, encompassing the penicillins, cephalosporins, carbapenems, and monobactams. Antimicrobial resistance to β-lactams has become common among many bacteria, so methods to optimize the pharmacodynamics of these drugs have been sought out to maximize their utility [101]. Studies have been done with several β-lactams administered as either continuous infusions or extended infusions [101]. Continuous infusions are self-explanatory; during extended infusions the drug is administered over several hours instead of the customary 15 or 30 min. This prolongs the time that the concentration is above the MIC of an infecting organism, potentially increasing the efficacy of the drug in difficult-to-treat infections [101, 102]. An increase in efficacy with piperacillin/tazobactam in *Pseudomonas* infections has been reported, and other β-lactams are being studied with this administration technique to maximize the type of organisms and infections that they are effective in treating [101, 102].

## 7 PHARMACOGENETICS

Pharmacogenetics studies the interplay between human genetic differences and the effectiveness of drug therapy [103]. In the development of anti-infectives, pharmacogenetics is most useful in studying the variance in the elimination of drugs since the agents need to be effective against target sites in bacteria, not humans. Pharmacogenetics is a growing area of study and few antibiotics have undergone extensive pharmacogenetic profiling [103]. An exception to this is isoniazid, a hepatically metabolized drug with high interpatient variability [104]. Some individuals slowly eliminate isoniazid from the body and are termed "slow acetylators," while "fast acetylators" are the opposite. Certain patient populations are known to generally fall into one of these categories, but specific genetic testing has been studied to determine how an individual will metabolize isoniazid before it is administered [105]. This is not yet widely used but serves as an example of future testing that can be performed to determine which patients are most likely to suffer adverse effects from particular toxic drugs before they are given. In the world of HIV therapy, a test is now used to determine which patients are most likely to have a hypersensitivity reaction to abacavir, a commonly used antiretroviral drug [106]. Pharmacogenetic tests are likely to be most useful for drugs with high degrees of toxicity that are either dangerous or that have adverse effects that are difficult to monitor pharmacodynamically.

## 8 DEVELOPMENT AS A CHANGING NEED

As patient populations change, new infectious agents emerge, and antimicrobial resistance advances, the target areas for new antibiotics evolve. In this section, we highlight antifungal development as an example of where this has taken place, highlighting the need to continue drug development as patient populations change.

### 8.1 Antifungal Development

Systemic fungal infections continue to become increasingly prevalent [107, 108]. Once dismissed as a contaminant in blood cultures, *Candida* species have become the fourth most common cause of bloodstream infections [108]. This is due to many factors [107]. The patient population within hospitals has become sicker due to increased life spans, improved outpatient management, and managed care decisions [107]. Chemotherapy regimens have become more effective in treating cancer, but cancer patients are immunosuppressed for long periods of time [107]. Organ transplantation has become more common and effective, also leading to increased immunosuppression [107]. All of these factors have led to a patient population that is increasingly susceptible to infection by fungi who infrequently affect healthier patients.

Amphotericin B deoxycholate was the first systemic agent that was widely used for the treatment of systemic fungal infections. It is effective against many fungi but has notable toxicities that are intolerable for many patients [107]. Most notable among these are nephrotoxicity and infusion-related reactions. Years after its introduction, pharmaceutical manufacturers sought to attenuate these toxicities by producing lipid formula-

tions of amphotericin B that were less nephrotoxic, and some have decreased infusion-related reactions [107]. Another class of antifungals, the azoles, were also developed to combat the rising incidence of fungal infections. Early agents were hampered by poor bioavailability or limited effectiveness, but as manufacturers saw the market for antifungals increasing, they responded by developing superior agents [107]. The first of these was fluconazole, a drug with very high bioavailability, minimal adverse effects, and excellent activity against many types of yeast [107].

Able to be taken orally and much less toxic than amphotericin products, fluconazole was a true advance in antifungal pharmacotherapy. However, it was not active against molds, a class of fungi that mainly infects only highly immunosuppressed patients [107]. As this population grew, itraconazole was developed to overcome the lack of mold activity of fluconazole. Itraconazole is active against many common molds, but its limitations were mainly pharmacokinetic [107]. Itraconazole has poor bioavailability in the original capsule formulation, and an intravenous formulation was not introduced for years after its introduction [107].

To address the shortcomings of itraconazole, voriconazole was introduced in the early 2000s. Voriconazole has excellent bioavailability and was available intravenously from its introduction [107]. Its manufacturer studied its utility in aspergillosis (the most common invasive mold infections) and showed superiority to the gold standard regimen of amphotericin B deoxycholate [109]. Though voriconazole has changed the way many mold infections are treated, there are still fungi against which it is not active, and posaconazole is the agent most recently introduced to the antifungal market to address some of these [110].

During the 1990s, the echinocandin class of antifungals was developed to address the issues of the increasing incidence of fluconazole-resistant *Candida* and to offer an alternative to amphotericin B formulations in the treatment of aspergillosis [107]. Marked by low toxicity, few drug interactions, and a broad spectrum of activity against yeasts and some molds, echinocandins were welcome alternatives to an antifungal market that had not seen a truly novel mechanism of action in several decades [88, 107]. Caspofungin was the first echinocandin to be marketed [88, 107]. After several years of market exclusivity, two other echinocandins were introduced: micafungin and anidulafungin [88]. All three of these agents are similar in terms of efficacy and safety, so a very competitive pricing market has developed.

These advances in antifungal development were led by the pharmaceutical industry's response to a growing need and resultant market. Development in antifungals had stalled for years before the echinocandins were introduced. The expansion of the immunocompromised population promises to result in a continued need for antifungal development for many years.

# ANTIMICROBIAL RESISTANCE IN BIOFILMS: A STICKY SITUATION

Shu Yeong Queck and Michael Otto
*National Institute of Allergy and Infectious Diseases, The National Institutes of Health, Bethesda, Maryland*

## 1 BIOFILMS—A CLINICAL AND INDUSTRIAL PERSPECTIVE

In many environments, microbial cells are found associated with surfaces and form conglomerate structures termed *biofilms* [1]. During human infections, the formation of biofilms has been implicated, for example, in periodontitis, otitis media, cystic fibrosis pneumonia, endocarditis, and osteomyelitis. In addition, biofilms are often found on indwelling medical devices such as prostheses and catheters, leading to a high incidence of infections associated with the use of such biomaterials [2]. It is estimated that at least 60% of all microbial infections involve biofilms [3]. For pathogens, the beneficial associations with biofilm formation include protection against stresses by antimicrobial agents and host defenses. As a consequence of its key role in pathogenesis, biofilm formation is a significant determinant of infectivity and persistence [3–5].

Outside the medical domain, biofilm formation causes serious problems for industries, particularly in food-processing and water distribution systems [6, 7]. For example, when biofilms are established on the interior of metal pipes in the production lines, accelerated corrosion of the pipes and contamination of pipe contents may occur. Additionally, increased tolerance of microorganisms in biofilms to disinfecting agents such as chlorine, peroxides, and quaternary ammonium compounds has been frequently reported. As a result, billions of dollars are spent annually to rectify biofilm-related repercussions in the industries [8].

The increased recognition of the impact that biofilm formation has in the clinical and industrial settings has led to an explosion in the field of biofilm research over the past two decades. These studies led to the generation of several hypotheses to account for the exceptional ability of biofilm populations to resist antimicrobial killings. In this review, the various mechanisms of antimicrobial resistance will be examined with a specific emphasis on the predominant pathogens involved in biofilm-associated infections, that is, staphylococci, *Pseudomonas aeruginosa*, and the fungal pathogen *Candida albicans*.

## 2 ANTIMICROBIAL RESISTANCE IN BIOFILMS DIFFERS FROM THAT IN PLANKTONIC CULTURE

It has become clear in several studies that mechanisms of resistance to antibiotics can differ significantly between biofilm and planktonic cells. A classic example is the resistance to β-lactam antibiotics such as ampicillin. In biofilms of *Klebsiella pneumoniae*, resistance to β-lactams was not correlated with the production of β-lactamase [9]. The penetration of ampicillin was impaired in the biofilms of wild-type cells, whereas biofilms formed by a β-lactamase mutant were fully penetrated by the antibiotic. Despite that, biofilm cells of the β-lactamase mutant were resistant to ampicillin, suggesting that mechanisms other than degradation by β-lactamase were responsible for the observed β-lactam resistance. The findings obtained in this and similar studies have prompted researchers to take a more detailed look at the specific mechanisms of antimicrobial resistance in biofilms (Fig. 1).

**Figure 1** Mechanisms of antimicrobial resistance in biofilms. (1) Penetration barrier. The penetration of some antimicrobials may be limited (reducing arrow) by their interactions with biofilm constituents (e.g. binding of antimicrobials to extracellular materials in the biofilm matrix and/or electrostatic repulsion between antimicrobials and the biofilm matrix). (2) Growth difference. Regions of biofilm exhibit different growth (light to dark; fast to slow growth), varying the efficacy of antimicrobials that predominantly target fast growing cells. (3) Biofilm physiology. The physiology of biofilm cells (■) is different from that of the planktonic (▬) counterparts (e.g. increased anaerobic respiration in biofilm cells), although some mechanisms of resistance may be similar to both modes of lifestyle. (4) Persister cells. The presence of persisters (⬭) that are resistant to a number of adverse environmental conditions.

## 3 RESTRICTIVE BARRIER TO ANTIMICROBIALS

The microbial biofilm matrix is a complex that consists primarily of water (up to 97%), microbial cells (2–5%), and a mixture of polymeric substances, which include polysaccharides, proteins, lipids, and nucleic acids [10, 11]. The matrix may act as a barrier in limiting the diffusion of molecules, including antimicrobial agents, into the biofilm, rendering biofilm cells resistant to antimicrobials. The presence of a diffusion barrier in biofilms has become evident in several early studies that showed limited penetration of antimicrobials into biofilms. For instance, the commonly used disinfectant chlorine was impaired in its penetration in a mixed *P. aeruginosa* and *K. pneumoniae* biofilm. Only 20% or less chlorine reached the deeper layers of the biofilm, compared to the bulk liquid [12]. Similarly, following treatment with monochloramine, a gradient of respiratory activity in the biofilm was observed. Cells in the deeper layer of the biofilm exhibited greater respiratory activity relative to lesser exposure to the biocide, compared to those at the biofilm–bulk liquid interface [13]. Finally, transport limitation of the fluoroquinolone antibiotic ciprofloxacin in *P. aeruginosa* biofilms was noted using attenuated total reflection/Fourier transform infrared (ATR/FT-IR) spectrometry [14]. However, the mechanism accounting for the limited penetration of the biocides into biofilms was not completely understood in these studies.

For some larger antimicrobials, the biofilm matrix may constitute a simple mechanical barrier. However, the penetration gradient of most antimicrobials in a biofilm is likely due to more specific interactions between antimicrobial agents with some of the biofilm constituents. For instance, sequestration by extracellular biofilm polymers may prevent the antimicrobial agents from penetrating to their targets. This has been reported for glucans in the periplasm of gram-negative bacteria [15]. A *P. aeruginosa* mutant disrupted in the synthesis of cyclic β-(1,3)-glucans formed biofilms that were more susceptible to the various antimicrobial agents tested. Furthermore, cationic aminoglycosides such as tobramycin have been shown to interact with the exopolysaccharide of *P. aeruginosa* [16], suggesting that the biofilm matrix may prevent the accumulation of antimicrobial agents by a sequestration mechanism that is likely dependent on electrostatic attraction.

In addition, electrostatic repulsion may account for limited penetration of antimicrobial agents in biofilms.

For example, resistance to cationic antimicrobial peptides (AMPs) in staphylococcal biofilms has been attributed to the unusual positive net charge of the staphylococcal exopolysaccharide. Polysaccharide intracellular adhesin (PIA) is a significant component of the staphylococcal biofilm matrix, consisting of β-1,6-linked glucosaminylglycan, which is synthesized and exported by the gene products of the intracellular adhesion (*ica*) operon [17, 18]. PIA production is important for biofilm formation, virulence, and protection of staphylococci against mechanisms of the human innate immune system, such as phagocytosis and killing by polymorphonuclear leucocytes (PMNLs), and human AMPs [19, 20]. Unlike most bacterial exopolymeric substances, PIA has an overall positive net charge due to the deacetylation of some of the *N*-acetylglucosamine monomers in the PIA polymer [20]. Due to the considerable addition of positive charges to the otherwise negatively charged staphylococcal cell surface by PIA, cationic antimicrobial agents (e.g., human AMPs LL-37 and β-defensin 3) are repelled, preventing their accumulation and access to cells within the biofilms. Together, these studies suggest that limited drug susceptibility in biofilms is at least in part due to interactions between biofilm constituents and antimicrobials, which prevent the penetration of drugs to their target site.

However, there are a number of studies to suggest that biofilm resistance is not solely due to a penetration barrier. For example, resistance to chlorine is likely not due to a penetration difference, as the diffusion coefficient of chlorine in biofilms is indistinguishable from that in pure water [21]. Similarly, biofilm resistance to antibiotics is not always due to limited penetration. For example, concentrations of the "last-resort" antibiotic vancomycin were detected in *Staphylococcus epidermidis* biofilms that exceeded the minimal inhibitory concentration (MIC) and minimal bactericidal concentration (MBC) for that organism [22]. Despite that, biofilm cells were not completely eradicated. Moreover, resistance to a variety of antifungal agents in biofilms of *Candida* species could not be explained by a penetration barrier [23]. Although the rate of penetration varied among the antifungal agents and the various biofilm species, all biofilms were fully penetrated by the antifungal agents tested, often at several folds above their MIC. Furthermore, drug resistance was evident in all the fungal biofilms examined. Therefore, the penetration of many antimicrobial agents is not limited in biofilms, and, thus, additional biofilm-specific mechanisms must be involved in the resistance of cells to those antimicrobials.

Taken together, the penetration of antimicrobial agents in biofilms is dependent on a multitude of factors, notably the structures of the biofilm matrix molecules and antimicrobial agents. Furthermore, it has become evident that the exceptional resistance of biofilm cells to antimicrobial agents is not only due to the restrictive barrier function of the biofilm matrix but that other mechanisms are involved.

## 4 A GRADIENT OF GROWTH

Cells in different zones of a biofilm grow at different rates. There is usually an inverse relationship between biofilm depth and growth activity. For example, biofilms of *K. pneumoniae* stained with acridine orange (nucleic acid stain) revealed spatial patterns of fluorescence [24], revealing that cells located within the deeper regions of the colony exhibited lower growth and vice versa. Not surprisingly, the availability of nutrient plays a major role for the development of such a gradient in growth. Sternberg et al. investigated the growth of cells in biofilms using a reporter fusion system. By tagging the growth-rate-regulated *rrnB*P1 promoter to a green fluorescent protein (GFP) reporter, the growth of *Pseudomonas putida* biofilms, ranging from individual cells to microcolony structures, was monitored. During the initial stages of biofilm development (e.g., attachment and surface colonization), similar intensity of fluorescence in cells was noted throughout the structures. As the biofilms matured, cells in the deeper regions exhibited reduced fluorescence (i.e., lower metabolic activities) relative to those closer to the biofilm–bulk fluid interface, displaying a gradient of growth differences. Part of this growth gradient observed was attributed to a depletion of nutrients as the biofilms expand. This hypothesis was supported by the fact that the gradient intensity became less pronounced upon introducing fresh nutrient [25]. These differences in growth may in part be due to the oxygen gradient that has been observed in biofilms. The levels of oxygen were significantly lower in the deeper regions of the biofilms compared to those closer to the bulk liquid interface [26].

As many antimicrobial agents are only active toward metabolically active cells, growth differences have a dramatic impact on antimicrobial resistance. In fact, several studies have correlated antimicrobial resistance with the metabolic status of cells in a biofilm. Such a correlation has been found both for those antimicrobial agents that result in the killing of the organism (e.g., by inhibition of cell wall synthesis such as by β-lactam antibiotics) and those that inhibit the organism's ability to propagate further (e.g., by inhibition of protein synthesis such as by tetracyclines). For instance, in *P. aeruginosa*, the regions in a biofilm in which antibiotics showed

the most pronounced activity corresponded to the sites of oxygen repletion and active metabolism, that is, the outer regions of the biofilm [27–29]. Interestingly, as the metabolic activity of biofilms of the fungus *C. albicans* increases rather than decreases with age, mature biofilms of *C. albicans* are more resistant to antimicrobials than younger biofilms—in contrast to what has been observed in bacteria [30]. However, these observations appeared to be rather specific for the *Candida* species among eukaryotic biofilms, as no such correlation could be established for biofilms of *Sacchromyces cerevisiae.* Thus, while the specific characteristics of growth-dependent biofilm resistance may differ from species to species, it appears that, in general, antimicrobial resistance in biofilms is due to a large extent to the reduced growth activity of the main biofilm body.

## 5 PHYSIOLOGICALLY DISTINCT POPULATION

We have seen that growth conditions and biofilm structure significantly affect biofilm resistance. In addition, recent global analysis of gene and protein expression has allowed us to determine specific factors that contribute to the resistance of biofilm communities to antimicrobials. Frequently, these factors determine the specific physiology of a biofilm and represent regulators that control the adaptation to the physiological requirements of biofilms. In addition, they may include resistance factors expressed during planktonic growth, but whose production or significance is greater in biofilms.

As a major result of transcriptome and proteome analyses, we now know that active, aerobic metabolism is reduced in bacterial biofilms, which is likely a consequence of the low levels of oxygen that have been reported in biofilms. Accordingly, in several studies, it has been found that genes involved in anaerobic respiration were upregulated in biofilms, while those associated with aerobic respiration were among those repressed [31–35]. As outlined above, the dormant state of cells in biofilms may mediate resistance to antimicrobial agents, particularly those that target growth-specific factors. In contrast to those earlier studies, however, biofilm resistance as a consequence of a shift in metabolism could now be pinpointed to specific genes and proteins. For instance, the enzyme formate dehydrogenase, a typical component of fermentative metabolism, is upregulated in biofilms of *Staphylococcus aureus*. The by-products of formate metabolism that are generated at an increased rate by formate dehydrogenase activity may generate an acidic milieu in biofilms, thereby reducing the efficacy of some antimicrobial agents [31, 34, 35]. In *P. aeruginosa*, the *nir* and *nap* gene clusters, which are required for respiratory nitrate reduction were upregulated in biofilms [33]. Anaerobic respiration is an important physiological adaptation in the pathogenesis of *P. aeruginosa*, in particular, for persistence in the hypoxic mucus environment of the airway lumens in cystic fibrosis [3, 36, 37]. Furthermore, the efficacy of aminoglycosides, such as tobramycin, is greatly reduced under anaerobic conditions. As we have noted already, in contrast to bacterial biofilms, cells in *C. albicans* biofilms are metabolically active [38–40]. Of particular interest in *C. albicans* biofilms is the increased expression of genes/gene products associated with sulfur metabolism, which is closely linked to the metabolism of glutathione, a molecule involved in the protection from oxidative stress in yeasts and filamentous fungi [41]. It has been suggested that glutathione may cause resistance to antifungal agents in *C. albicans* biofilms [39] as the alteration in glutathione levels has previously been correlated with the resistance of the eukaryotic pathogen *Plasmodium falciparum* to antimalarial drugs [42]. Hence, these studies suggest that the specific characteristics of biofilm physiology may reduce susceptibility to some antimicrobial agents.

Multidrug efflux pumps (MDPs) are involved in the extrusion of a wide spectrum of antibiotics such as aminoglycosides and cationic antimicrobial peptides [43]. Whereas in planktonic population their contribution to antimicrobial resistance has been well established, it is not known whether they contribute to antimicrobial resistance in biofilms. Although the genome of *P. aeruginosa* contains at least 10 MDPs [44], only 6 of them have been identified as important for antimicrobial resistance. Moreover, none of these 6 MDPs were differentially regulated in biofilms, suggesting that MDPs do not contribute to biofilm resistance in *P. aeruginosa* or resistance is due to yet uncharacterized MDPs [32, 45]. However, there appears to be a temporal role for MDPs in the resistance to antifungal agents in biofilms of *C. albicans* [46, 47]. For example, while there is no evidence for a role of MDPs in resistance to antifungal agents during the later stages of *C. albicans* biofilm development, MDP-mediated resistance to fluconazole is confined to planktonic and young (6 h) biofilm communities. In conclusion, however, there is currently no clear evidence to indicate a general involvement of MDPs in the antimicrobial resistance of biofilms, and, thus, these studies underline the notion that resistance mechanisms differ significantly between the planktonic and biofilm modes of growth.

Recent advances in our understanding of biofilm-specific physiology and gene expression suggest that the differential expression of regulatory factors plays a major role in biofilm resistance. Notably, several global regulators, such as those involved in the control of stress

response and expression of virulence determinants, are differentially regulated in biofilms. For instance, the environmental and infection stress response sensor, ClpC, which has previously been shown to be crucial for biofilm formation [48], was highly expressed in biofilms of *S. aureus*. ClpC and other Clp proteins belong to a family of closely related proteins, the Hsp100/Clp ATPases, which carry out diverse cellular functions. For example, they function as chaperones and are involved in the proteolysis of incorrectly folded protein substrates and the regulation of transcription [49]. In *S. aureus*, the Clp proteins have been shown to mediate stress responses (e.g., thermotolerance and salt tolerance) and replication in epithelial cells [48]. In addition to ClpC, the levels of other chaperones and oxidative stress proteins were higher in staphylococcal biofilms [34, 35]. Interestingly, major regulators of virulence in staphylocci, such as *agr* and *sarA* were downregulated in biofilms, causing lower levels of toxins and protease production in biofilms [34, 35, 50]. The loss in these regulator functions in staphylococci has previously been correlated with reduced activation of the host immune defense and resistance to antimicrobial agents [51–53]. In *P. aeruginosa*, the *Escherichia coli* stationary phase sigma factor, RpoS, was repressed in biofilms [32]. Although RpoS is responsible for the induction of starvation stress resistance and virulence response in *E. coli*, its role appears to control virulence in *P. aeruginosa* [54, 55]. RpoS predominantly induces genes coding for proteins involved in chemotaxis and two-component systems, whereas several heat shock proteins and secreted factors are among those repressed. Although the expression of RpoS has been correlated with the resistance of *P. aeruginosa* biofilms to tobramycin, the role of this sigma factor in biofilm resistance to antimicrobial agents is still poorly understood [32, 56]. Finally, recent studies have indicated a key role of cylic diguanosine monophosphate (c-di-GMP) in the control of switching bacterial physiology between the biofilm and planktonic modes of growth. Although the specific targets of c-di-GMP control remain yet to be determined, it is known that c-di-GMP is important for a number of cellular processes, including cell differentiation, multicellular behavior, and expression of virulence traits in a number of bacterial species [57]. The aminoglycoside response regulator (*arr*, formerly PA2818) of *P. aeruginosa* induces resistance to aminoglycosides and biofilm formation through the modulation of the intracellular levels of c-di-GMP [58]. Thus, it appears that increased levels of c-di-GMP lead to increased antimicrobial resistance by switching physiology to the typical physiological status of a biofilm. Taken together, these studies indicate that a variety of regulatory changes make biofilm cells better equipped than their planktonic counterparts to encounter adverse conditions.

Not surprisingly, a number of resistance mechanisms shown to protect planktonic cells from antimicrobial agents were also adopted in biofilms. However, in some cases there appears to be a more pronounced role of some mechanisms of resistance in the biofilm mode of growth, which may contribute to the overall higher antimicrobial resistance of biofilms. For instance, genes that code for specific proteins required for the synthesis of poly-γ-glutamate (PGA) complex in *S. epidermidis* were upregulated in biofilms [50]. PGA mediates high salt tolerance and protection from major components of the human immune system, including killing by antimicrobial peptides and PMNLs. Moreover, PGA is crucial for the persistence of *S. epidermidis* in device-related infections [59]. In *C. albicans*, resistance to antifungal agents in planktonic cells has been associated with alterations in the sterol composition of the cell membrane [60]. In biofilms, the low ergosterol levels and reduced transcript level of genes involved in ergosterol biosynthesis were found to correlate with increased resistance to antifungal agents such as amphotericin B and fluconazole [47, 61]. In addition, a number of proteins are expressed at higher levels in biofilms of clinical isolates that were resistant to azole antifungal agents [62]. Hence, these studies suggest that some resistance mechanisms that have previously been described in cells grown in planktonic culture play a crucial and possibly more important role in biofilm communities.

## 6 CONTRIBUTIONS OF THE PERSISTERS

A relatively new and controversial hypothesis claims that a subpopulation of dormant cells exists in biofilms that determines antimicrobial resistance. These cells have been called "persisters." Similar to spores and other resistant structures, persisters grow slower than the wild-type cells but are better at withstanding adverse environmental conditions such as those encountered during antibiotic treatment. Therefore, persisters may contribute to the continual propagation of the biofilm progeny following exposure to antimicrobial agents, resulting in recalcitrant infections [63]. Notably, persister cells are genetically identical to cells in the bulk population and are not exclusive to biofilms [64, 65]. Although they are typically present in higher numbers in stationary phase growth, cultures in earlier growth phases also contain persisters, emphasizing their specific and unique physiological status.

While there are many reports of persister cells in gram-positive and gram-negative bacteria, and recently *C. albicans* [66], little is known about the mechanism of

drug resistance conveyed by persisters and the regulation of persister cell formation. Recently, several multiple drug tolerance (MDT) genes were identified to be important for the generation of persister cells in *E. coli* [67, 68]. These genes include a presumable toxin/antitoxin module encoded by *hipBA* and genes involved in sn-glycerol-3-phosphate metabolism, in particular, the enzyme sn-glycerol-3-phosphate dehydrogenase, which is encoded by *glpD*. Importantly, the deletion of either of these gene loci resulted in a lower frequency of persister cells in stationary phase, while induced expression of their gene products enhanced the tolerance of the cell population to a range of antimicrobial agents [67, 68]. However, the modes of action of MDT genes are still elusive. According to one model, the toxin HipA offers a "protective" effect by binding to the cellular target sites of antimicrobial agents [63]. In this model, the binding of the toxin alters functionality of the target (e.g., ribosome), rendering it insensitive to the actions of the specific antimicrobial agent, thereby generating tolerance in cells. Furthermore, it has been suggested that the MDT genes involved in persister cell formation may be different among species. For example, although multiple drug-tolerant persister cells made up about 1% of the population in stationary phase *P. aeruginosa* cultures, no homologs of *hipBA* were found in this organism. Hence, more detailed investigation of the mechanism underlying the generation and MDT of persister cells in other organisms is warranted.

In *P. aeruginosa*, staphylococci and other bacterial species, another type of persister cells termed small colony variant (SCV) is frequently reported [69, 70]. Contrary to the persisters described by Lewis [63], SCVs of *P. aeruginosa* are heterogenous in growth and are typically isolated from biofilm cultures. Moreover, SCVs are often implicated in bacterial pathogenesis as they exhibit MDT levels several folds higher than the corresponding wild-type strains and may cause more persistent infections. Indeed, SCVs and biofilm formation have been made accountable for the persistence of *P. aeruginosa* in the lungs of cystic fibrosis (CF) patients despite long-term antibiotic therapy [3, 71–73]. Several recent studies have led to a better understanding of SCV development, the molecular mechanism underlying the generation of the RSCV phenotype, and its correlation with antibiotic resistance, and biofilm formation in *P. aeruginosa* [74]. The phenotype variant regulator, *pvrR*, was found to exhibit a multitude of functions, including the regulation of the switch in rough SCV (RSCV) to wild-type phenotype, attachment, and biofilm formation. More recently, Webb et al. proposed a model to explain the generation of SCVs in biofilms of *P. aeruginosa* by the involvement of the filamentous phage Pf4 [75]. The analysis of the Pf4 phage sequence revealed the presence of a toxin/antitoxin module and several genes that may contribute to the SCV phenotype. Similarly, small colony formation in *E. coli* has been attributed to filamentous phage infection [76]. Furthermore, transcriptional profiling of gene expression has revealed that a number of phage-related genes in *P. aeruginosa* were upregulated in biofilm communities [32, 33]. These findings suggest a general role for phage involvement in the generation of SCVs and bacterial biofilm development.

SCVs in staphylococci are different from those of *P. aeruginosa* and the persister cells described by Lewis [63]. Staphylococcal SCVs are slow growing and their emergence is often linked to mutations in metabolic pathways in response to challenges by antimicrobial agents, generating auxotrophs [77, 78]. The most commonly isolated and best characterized staphylococcal SCVs are those deficient in electron transport (ET) and thymidine biosynthesis. Compared to their isogenic parental strains, these SCVs are more resistant to cell wall specific agents such as β-lactam antibiotics and display reduced sensitivities to cationic agents such as aminoglycosides [79]. Deficiency in the ET pathway in staphylococcal SCVs can be caused by mutation in one of several single-gene loci [80–82]. For example, mutation in *menD* disrupts the synthesis of menadione, which in combination with isoprenoid lipid is required for the synthesis of menaquinone. Mutations in *hemB* and *ctaA* affect the synthesis of heme, which disrupts cytochrome biosynthesis. Comparatively, the genetic basis of thymidine-auxotrophic (TA) SCVs is still poorly characterized. TA SCVs are prevalent and highly persistent in the airway secretions of CF patients on long-term therapy with trimethoprim sulf-amethoxazole [83, 84].

Clinically, SCVs of staphylococci are involved in a multitude of persistent infections such as cystic fibrosis, osteomyelitis, and device-related infections [70]. SCV formation is crucial for staphylococcal pathogenesis, as SCVs exhibit enhanced persistence in host tissues [82, 85–87]. This is likely due to two factors that result in immune evasion: enhanced internalization into host cells and diminished expression of aggressive virulence factors such as hemolysins, leukocidins, and extracellular proteases [88, 89]. Additionally, in most of the staphylococcal TA SCVs, the expression of a number of major virulence regulators including *sarA*, the *agr* quorum sensing system, and the alternate sigma factor *sigB*, is decreased [90], which leads to a shift in virulence factor production. This loss of regulator function has been previously linked to reduced activation of host defenses and resistance of staphylococci to antimicrobial agents [51–53]. Interestingly, Vaudaux et al. showed that the observed enhanced internalization of staphylococcal SCVs by host cells may be due to higher expression of

surface adhesins, including fibronectin and fibrinogen-binding proteins, which play an important role during the internalization process [87]. Taken together, immune evasion by the generation of SCVs appears to represent one of the reasons for recalcitrant biofilm-associated staphylococcal infections.

## 7 NOVEL APPROACHES TO THE "STICKY PROBLEM"

Two approaches, namely prevention and eradication, have been proposed for the control of biofilm-related infections. First, making the surfaces less favorable for microbial colonization may prevent biofilm formation on medical devices. This may be achieved by the alteration of the physicochemical properties of the surface or by coating with substances that inhibit bacterial growth and/or biofilm formation. Second, biofilms may be disrupted after their formation, thereby converting bacterial communities to single cells, which can be more efficiently attacked by conventional antibiotics. This section will highlight some of the recent advances made with regard to preventing and removing microbial biofilms on surfaces.

### 7.1 Quorum Sensing Inhibitors

The term *quorum sensing* (QS) was initially coined to describe the regulation of bacterial gene expression in a cell-density-dependent fashion [91]. Recently, the QS phenomenon has also been described in fungi [92]. Notably, in many organisms QS has been shown to influence biofilm development. This has become clear in several studies that investigated phenotypic differences in the biofilms formed by QS mutants compared with their isogenic wild-type strains [93].

It has been frequently reported that a group of compounds termed furanones, which are produced by the marine algae *Delisea pulchra*, act by competing with acylated homoserine lactone (AHL)-type QS signals for binding to the cognate response regulator, thereby inhibiting QS controlled phenotypes [94–97]. Although the primary target of the furanones is the AHL regulatory system (AI-1) in gram-negative bacteria, they also appear to interfere with an alternative signaling system, AI-2, that is prevalent in gram-positive and gram-negative bacteria [98, 99]. In *P. aeruginosa*, furanone treatment resulted in the attenuation of QS-controlled virulence factor expression, causing a reduction in biofilm formation and the severity of infection [100, 101]. In addition, the pretreatment of biomaterials with furanones provided protection from microbial colonization and biofilm formation [102, 103]. Importantly, at least in gram negatives, the mechanisms of furanones are neither bacteriostatic nor bactericidal [104], which is believed to minimize the development of microbial resistance to these compounds.

The inhibition of QS control has also been suggested as a means to inhibit biofilm formation in eukaryotes. For example, the fungal pathogen *C. albicans* uses farnesol as a QS signal to regulate filamentation and biofilm formation [105, 106]. Transcriptional profiling of gene expression in *C. albicans* biofilms after treatment with farnesol revealed that many factors that may contribute to biofilm persistence, such as heat shock proteins, genes involved in cell wall maintenance, and genes associated with drug resistance were downregulated [107]. In addition, farnesol was shown to be active against other microbes [108, 109] and influenced, for example, the induction of apoptosis in *Aspergillus nidulans*, enhanced antimicrobial susceptibility, and inhibited biofilm formation in *S. aureus*. Thus, farnesol may be applicable in the control of biofilms formed by fungi and mixed bacterial–fungal populations.

While the idea of using QS antagonists offers a promising outlook in the combat of microbial biofilms, caution should be exercised when using such agents for therapeutic purposes. For example, furanones are structurally similar to the AHL molecules [104], which in addition to their regulatory role, possess immunomodulatory activity that can alter the outcome of an immune response [110–114]. Thus, the administration of high levels of furanones may potentially trigger undesirable immune consequences in the human host, leading to more severe development of certain diseases. Also, the effect of QS regulation in virulence and biofilm formation varies among microbes. For instance, the *agr* QS system in staphylococci negatively regulates biofilm formation [115, 116]. In addition to enhanced biofilm formation, interfering with QS signaling in staphylococci might drive undesirable consequences including persistence in device-related infections [117] and reduced susceptibility to antimicrobials [52, 53]. Hence, interfering with QS control as a therapeutic means to treat biofilm-associated infection should take into account the dosage of compounds administered and the specific pathogen and type of infections involved.

### 7.2 Enzymatic Treatment

Polysaccharides are among the most intensively studied components of the microbial biofilm matrix [10, 11]. Notably, they often represent an indispensable component of this matrix and thus are common targets in strategies aimed to disrupt microbial biofilms. An important example is the exopolysaccharide alginate of *P. aeruginosa*. *P. aeruginosa* strains that are isolated from

the lungs of CF patients frequently have a mucoid phenotype. The formation of mucoid has been attributed to the production of alginate, which appears to have a key role in pathogenesis, as it provides a protective barrier against the host's immune defense and antibiotic treatment [118]. The enzyme alginate lyase (AlgL), encoded as part of a 12-gene operon for alginate biosynthesis in *P. aeruginosa*, is likely involved in the degradation of periplasmic alginate polymers and their secretion to the outer membrane [119]. Mutation in *algL* led to rapid cell burst due to the accumulation of the alginate polymers in the periplasm. Therefore, alginate lyase has been suggested as a potential therapeutic for mucoid *P. aeruginosa* infection. In such an effort, Alkawash et al. showed recently that following treatment with exogenous alginate lyase, alginate was rapidly degraded in biofilms of mucoid *P. aeruginosa* [120]. The coadministration of alginate lyase with antibiotics also greatly enhanced the efficacy of the antimicrobial agents in the clearance of mucoid *P. aeruginosa* biofilms, suggesting that the incorporation of alginate lyase into an antibiotic regime may provide a better prognosis in the treatment of CF.

Staphylococci are among the most common group of microbes implicated in device-related infections [116, 121]. Although recent reports have suggested that in some cases, staphylococcal biofilms may be formed without the involvement of the exopolysaccharide PIA [122], the importance of PIA in staphylococcal biofilms and infections has been well established [123–125], making it an ideal target for antibiofilm therapy. One such approach is the use of the enzyme dispersin B, an *N*-acetyglucosaminidase produced by the gram-negative bacterium *Actinobacillus actinomycetemcomitans* [126]. Dispersin B specifically degrades PIA into its *N*-acetylglucosamine monomers [17, 18]. As a consequence, the addition of dispersin B resulted in the rapid disruption of intracellular adhesion within *S. epidermidis* biofilms, while pretreatment of surfaces with the enzyme prevented biofilm formation [126]. Interestingly, homologs of genes responsible for the biosyntesis of PIA have been found in other bacteria, such as *E. coli* [127] and *Yersinia* species [128], indicating that dispersin B may exhibit activity against other important biofilm forming organisms. As another example, therapeutic use of the cell wall lytic enzyme lysostaphin has been proposed for the control of *S. aureus* biofilms and infections. This enzyme specifically targets the pentaglycine cross bridges in the cell wall of *S. aureus* [129]. Although *S. epidermidis* has a certain degree of natural resistance to lysostaphin, which is due to the exchange of glycine residues with serine in the pentapeptide, biofilms of both *S. aureus* and *S. epidermidis* were disrupted by lysostaphin, and pretreatment of catheters with the enzyme prevented staphylococcal biofilm formation [130, 131]. Furthermore, the incorporation of lysostaphin in the treatment regime resulted in the eradication of diseases such as staphylococcal keratitis and endocarditis in several animal models [132–135]. However, although enzyme-based approaches may appear promising and elegant in vitro and in animal infection models, proteolytic instability and antigenicity may in general limit their applicability for the treatment of human infection. This may be the case specifically for lysostaphin, whose immunogenicity seems to limit the potential use of this enzyme for the treatment of staphylococcal infections [136].

### 7.3 Bacteriophage

The coexistence of bacteriophage and bacteria in biofilms has been established in a number of studies [137]. In addition, bacteriophages may cause the lysis of cells in biofilms of gram-positive and gram-negative bacteria [75, 138, 139], paving another alternative in biofilm control. Two recent reports have demonstrated the feasibility of using bacteriophage in combating biofilm infections. The pretreatment of catheters with an *S. epidermidis* bacteriophage resulted in a significant reduction in the formation of biofilms [140]. These results were encouraging and highlighted the prospect of bacteriophage coatings on biomaterial as a means to reduce device-related infections, although these initial findings need to be confirmed by in vivo studies. In the second study, a bacteriophage was used as a delivery tool for administering chloramphenicol to *S. aureus* [141]. Essentially, a high concentration of a chloramphenicol prodrug was conjugated to a bacteriophage, which remains inactive when bound to the phage. Upon interacting with the target *S. aureus* cells, a high dosage of chloramphenicol was delivered via enzymatic cleavage of the prodrug, resulting in severe retardation of *S. aureus* growth. As we have seen in previous chapters, the failure to eradicate microbial biofilms may in part be attributed to an insufficient concentration of antimicrobial agents that reaches the target [142, 143]. In that respect, such a use of biofilm-penetrating bacteriophage may be helpful in increasing the effective concentration of antibiotic and thus eradicating microbial biofilms.

## 8 CONCLUDING REMARKS

Antimicrobial resistance is one of the major reasons for which life in a biofilm is advantageous for microbes over the free-floating mode of growth. Notably, it allows pathogens to persist during human infection for prolonged periods and cause chronic infections that are often extremely difficult to eradicate.

We have outlined here how the formation of biofilms causes an increased resistance to antimicrobials, including microbicidal molecules of innate host defense and agents used during antibiotic therapy. We have seen that this increased resistance is due to a number of different mechanisms, of which presumably the most crucial and widely spread are the reduction of active metabolism and the production of a protective extracellular barrier. In addition, some microbes have specific mechanisms of resistance, which include for example the enzymatic degradation of antimicrobial substances.

The more recent advances in genomic and proteomic analyses of microbial gene and protein expression, and their application to the investigation of biofilm physiology, have already yielded a vast amount of data, and it is to be expected that similar studies will be performed to include more microorganisms and modes of biofilm growth. While the synoptic interpretation of these results still suffers somewhat from the lack of standardization with regard to biofilm models, we will certainly gain a much better understanding from these studies of how details of biofilm physiology affect antimicrobial resistance.

Current efforts to find treatments for biofilm-associated infections frequently aim to develop compounds for the inhibition of biofilm formation, which would be applied in combination with conventional antibiotics to kill biofilm-forming organisms. Directly interfering with the mechanisms of biofilm antibiotic resistance would represent a variation of this strategy. However, as we have seen, the mechanisms of biofilm resistance to antimicrobials are diverse, and, thus, biofilm resistance is probably best attacked by eliminating biofilm formation as a whole. Additionally, structures that are indispensable for the formation of a biofilm, such as the polysaccharide intercellular adhesin, are often also crucial for antimicrobial resistance. Therefore, understanding the molecular basis of biofilm resistance may assist us in providing potential lead substances in the endeavor to find new treatments for biofilm-associated infection.

# DROTRECOGIN ALFA ACTIVATED (RECOMBINANT HUMAN ACTIVATED PROTEIN C, XIGRIS)

Byungse Suh and Rafik Samuel
*Section of Infectious Diseases, Temple University School of Medicine, Philadelphia, Pennsylvania*

Our understanding of the immunopathophysiology of sepsis has made extraordinary progress during the past several decades, although therapeutic advances during the similar period have been extremely slow. During the past decade several clinical trials demonstrated promising results showing reduced morbidity and mortality in sepsis, although some had mixed outcomes. These trials have supported four major approaches: (1) maintenance of good tissue oxygenation by aggressive management of fluid and blood transfusion, (2) intensive insulin therapy to maintain the euglycemia, (3) low-dose corticosteroids, and (4) treatment with human recombinant activated protein C (drotrecogin alfa activated, Xigris, Eli Lilly and Company, Indianapolis, IN). These options will be briefly summarized below, but this chapter will concentrate on the epidemiology, pathophysiology, and management of sepsis with emphasis on the use of drotrecogin alfa activated (DAA) in the management of sepsis.

## 1 INTRODUCTION

In 1991, the American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM) held a "Consensus Conference" to define the terms *sepsis* and *organ failure* in a precise manner. At the conference, the term *systemic inflammatory response syndrome* (SIRS) was developed representing a clinical response arising from a wide variety of nonspecific insults [1]. The syndrome complex includes, but is not limited to, more than one of the following: (a) a body temperature of >38°C or <36°C; (b) a heart rate of >90 beats/min; (c) tachypnea, as manifested by a respiratory rate of >20 breaths/min or hyperventilation, as indicated by a $PaCO_2$ of 32 Torr (<4.3 kPa); and (d) an alteration of the white blood cell (WBC) count of >12,000 cells/$mm^3$, or <4000 cells/$mm^3$, or the presence of >10% immature neutrophils ("bands"). *Sepsis* is defined as having SIRS with proven or highly suspected infection, while sepsis associated with organ dysfunction, hypoperfusion, or hypotension is defined as *severe sepsis*. Furthermore, *septic shock* is referred to sepsis with hypotension [a systolic blood pressure (BP) of <90 mmHg or reduction of >40 mmHg from baseline], despite adequate fluid resuscitation, along with the evidence of tissue hypoperfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status [1]. The introduction and use of these definitions were not without criticism for making the situation more confusing, and the term SIRS is nonspecific and too sensitive [2]. A decade later, in 2001, the 1992 original document [1] was revisited by the expert members of the SCCM, the ACCP, the European Society of Intensive Care Medicine (ESICM), the American Thoracic Society (ATS), and the Surgical Infection Society (SIS), and found no evidence to support a change to the definitions [3]. Therefore, in this chapter the 1992 consensus definitions will be used.

## 2 EPIDEMIOLOGY OF SEPSIS

Review of the epidemiology of sepsis in the United States during the past several decades strongly indicates that the incidence of sepsis and the absolute number of sepsis-related deaths are increasing [4, 5]. There were 164,000 and 660,000 cases of sepsis in 1979 and 2000, respectively, which translate into approximately 8.7% annual increase in the incidence of sepsis [5]. A best estimate for the national annual incidence of severe sepsis has been reported to be 751,000 with a mortality rate of 28.6% (215,000) and the average costs per case was $22,100 with annual total costs of $16.7 billion [6]. Mortality for the more severe septic shock is 58% [7]. It is estimated that incidence of sepsis will be more than 1 million cases per year in the U. S. by 2020 [6, 8].

## 3 PATHOPHYSIOLOGY OF SEPSIS

Since sepsis is a clinical syndrome representing a set of signs and symptoms occurring together or in sequence due to infection rather than a distinct disease entity, it is likely that there may be multiple pathophysiologic mechanisms. In fact, there have been multiple mechanisms proposed and some of them have been tested for the syndrome; some with success and some with failure. Therefore, the precise pathophysiologic mechanism underlying the syndrome is still poorly understood and most likely entails more than one mechanism. The interaction between invading microbial agent and their products such as endotoxin (lipopolysaccharide, LPS) and the host responses can be classified into two large categories: (1) local defense mechanism: walling off and killing invading microbes, and (2) systemic response mechanism: keeping infection and inflammation localized [9].

The local defense mechanism utilizes the involvement of tissue–resident macrophages, mast cells, and dendritic cells. These cells, by secreting mediators that mobilize the inflammatory response, can mount the defense mechanism at the local level, helping to wall off the tissue infection and minimize bloodstream invasion. In addition, neutrophils and Kupffer cells of the liver phagocytose and help eliminate the invading organisms, and this response is facilitated by host's both immune systems, that is, innate and acquired immunity [10, 11].

The current concept on the systemic response of host to infection, injury, and other stresses emphasizes the suppression of an inflammatory process within the bloodstream. The systemic responses are believed to be primarily regulated by the brain and the liver [9]. The central nervous system (CNS), upon receiving signals of microbial invasion through nociceptive and vagal nerves, rapidly activates the hypothalamus–pituitary–adrenal (HPA) axis. Thus, the autonomic nervous system and the hypothalamic thermoregulatory center are primed properly to minimize the inflammatory process and maximally curtail the microbial growth. At the same time, blood-borne mediators [interleukin-1β (IL-1β), interleukin 6 (IL-6), tumor necrosis factor (TNF), interferons, prostaglandin $E_2$] are transported to reach the hypothalamus to augment the above processes [9, 12].

The liver and the spleen play an essential role in systemic responses to infection. The liver filters the blood that may harbor microbes, leading to collection and killing the blood-borne microorganisms. At the same time, it senses low level of circulating mediators and communicates this information to the CNS. The spleen is the principal organ to filter and eliminate the opsonized microorganisms.

As the CNS receives information on sepsis, injury, and other stresses, it triggers the mechanisms of systemic responses in five major categories: anti-infective, anti-inflammatory, procoagulant, metabolic, and thermoregulatory processes [9]. Each category of mechanisms in theory contributes to limit the infection or injury.

Leukocytosis, through demargination by epinephrine and cortisol, and through mobilization of marrow reserve neutrophils by granulocyte colony stimulating factor (G-CSF) and other cytokines, is an example of the initial anti-infective mechanism. Furthermore, anti-inflammatory responses keep the demarginated neutrophils from adhering to uninfected tissues, and increase in blood levels of anti-inflammatory mediators such as IL-1Ra, soluble TNF receptors, epinephrine, cortisol, α-melanocyte-stimulating hormone (α-MSH), adrenocorticotropic hormone (ACTH), IL-4, IL-6, IL-10, IL-13, transforming growth hormone (TGF)-ß, C-reactive protein (CRP), protease inhibitors, and antioxidants [9]. Recent evidence suggests that the pro-inflammatory response as determined by the level of IL-1ß and/or interferon-γ is localized to the infection or inflammatory site, whereas anti-inflammatory response—as measured by the levels of Anti-IL-1 and Anti-TNF—is systemic [13, 14].

Circulating cytokines trigger the brain's normal adaptive thermoregulatory response to systemic inflammation with fever [15–17]. This is manifested by shivering and redirecting blood flow from the skin and extremities to internal organs by means of vasoconstriction [9]. This increase in body temperature may favor the survival of the host while inhibiting bacterial growth. Bactericidal activity of neutrophils and macrophages may be increased during the febrile period [18].

## 4 MANAGEMENT OF SEVERE SEPSIS

Septic shock can be managed aggressively and effectively by identifying the possible etiologic organism(s) and the most likely source of infection. Antimicrobial therapy remains the mainstay of therapy to improve the outcome of severe sepsis. Therefore, efforts to correctly identify the source and possible etiologic agent(s) should be sought early in the process. Any necessary surgical drainage should be performed as soon as possible, and adequate cultures must be obtained. Then the attention should be concentrated on stabilizing the cardiovascular, respiratory, and other organ systems in an intensive care setting, often with aggressive fluid resuscitation.

Once these items, such as antimicrobials, fluid resuscitation to maintain the blood pressure, vasopressor use, and adequate oxygenation have been put in place, adjunctive therapeutic measures to reduce the morbidity and mortality based on pathophysiology of sepsis may be contemplated. Therapeutic modalities that have been tried to improve the outcomes of patients with septic shock will be described briefly; some with positive outcome and some with disappointing outcomes.

## 5 INTENSIVE INSULIN THERAPY

It is well recognized that among various metabolic derangements in the early phase of shock, the hyperglycemia, as a result of glycogenolysis and gluconeogenesis mediated by glucocorticoids, glucagon, and catecholamines as well as the decrease in insulin, is commonly observed. Also, hy*po*glycemia may ensue in the late phase of shock due to glycogen depletion or failure of glucose synthesis in the liver [19]. In a recent clinical trial in critically ill surgical patients, it was demonstrated that intensive insulin therapy to maintain blood glucose at or below 110 mg per deciliter improves the outcome with reduced morbidity and mortality [20]. However, in a more recent study, well designed with larger patient population that investigated the role of intensive insulin therapy in patients with severe sepsis, failed to demonstrate improved outcomes. Rather, the intensive insulin therapy group had more serious adverse effects related to hypoglycemia with no improvement in mortality [21]. Therefore intensive insulin therapy in sepsis will need to be reassessed.

## 6 USE OF STEROIDS

It is well understood that the host responds to stress/injury including that due to sepsis with an activation of the HPA axis that results in increased hydrocortisol levels. A possible poor prognostic indicator for patients in septic shock may be an inadequate rise in hydrocortisol after a corticotropin stimulation test [22]. Based on this hypothesis, a double-blind, placebo-controlled, randomized, and multicenter clinical study was performed to see whether low doses of corticosteroids (50 mg intravenously/6 h for 7 days and 50 μg of 9-α-fludrocortisone) in patients with septic shock would improve the 28-day survival [23]. When a total of 229 nonresponders were analyzed (placebo, 115; corticosteroid, 114), a lower mortality (53%) was seen in the corticosteroid group compared to the mortality (63%) in the placebo group. On the other hand, a similar analysis of 70 responders (placebo, 34; corticosteroid, 36) demonstrated no such effect; the 28-day mortality for the placebo and corticosteroid group were 53 and 61%, respectively. A meta-analysis of the effect of steroids on survival in septic shock during the period of 1963–2002 indicated that survival depends on the dose of steroid; high dose (e. g., methylprednisolone, 30 mg/kg of body weight, in four intravenous doses over 24 h) is detrimental, whereas low dose (e.g., 200–300 mg of hydrocortisone in four intravenous doses over a 24-h period for 5 days) increases the survival rate and shock reversal [24]. To validate the beneficial effect of low-dose steroids in patients in septic shock, a larger scale study on the patient population consisting of 254 corticotropin responders (hydrocortisone, 125; placebo, 108) and 233 nonresponders (hydrocortisone, 118; placebo, 136) has been undertaken [25]. The results, however, failed to demonstrate a beneficial effect of low-dose steroids in either patient population. Perhaps the use of corticosteroid may only be justified in those patients in septic shock which is resistant to high-dose vasopressors [23].

## 7 ENDOTOXIN-NEUTRALIZING PREPARATIONS

It is well recognized that endotoxin (LPS), a glycolipid outer membrane component of gram-negative bacteria, produces the typical features of gram-negative sepsis syndrome [26, 27]. Neutralization of endotoxin, therefore, should minimize the septic process in theory. HA-1A, a human monoclonal IgM antibody that binds to the lipid A domain of endotoxin, has been shown to reduce mortality in patients with septic shock from gram-negative bacteria from 57 to 33% when compared with placebo [28]. Nevertheless, a well controlled canine model of gram-negative septic shock failed to support the above study in that the HA-1A-treated group had a higher mortality (HA-1A group, 85%; control group, 43%) [29]. Another controlled clinical trial with E5

murine monoclonal IgM antibody to endotoxin revealed that only the patients who were not in shock seemed to have benefited from antibody therapy with improved survival and reversal of organ failure. A similar benefit was not seen in patients who were in shock [30]. Furthermore, in 2000 a study of over 900 patients with confirmed gram-negative sepsis investigated the efficacy of an E5 murine monoclonal antibody preparation. The study was prematurely stopped after an interim analysis showed no significant efficacy [31]. Current endotoxin monoclonal antibody preparations, either human or murine, have all failed to show benefit.

## 8 ANTI-INFLAMMATORY/ IMMUNOMODULATING AGENTS

In addition to low-dose corticosteroid use as described above, high-dose corticosteroids as anti-inflammatory agents have been studied in septic shock. No study showed benefit and some showed harm [32–35]. A randomized, double-blind, and placebo controlled study to investigate the effects of ibuprofen (10 mg per kilogram body weight given intravenously for 8 doses), a potent cyclooxygenase inhibitor and anti-inflammatory agent, in severe sepsis patients failed to improve the overall patient population [36]. However, when the subpopulation of patients with hypothermia was analyzed, there was a significant improvement in survival (ibuprofen group, 54%; control group, 90%). Several studies have shown that patients with severe sepsis who are hypothermic (<35°C) have almost twice as high mortality as patients with normal or elevated temperature [37, 38].

Since the early 1990s, immunomodulatory agents such as interleukin 1 receptor antagonist [39] and tumor necrosis factor receptor fusion protein [40] treatment have been studied in patients with septic shock and failed to improve survival. Also, in a severe sepsis animal model, mortality in complete knockout IL-6 (IL-6KO) animals was no different from wild-type animals [41]. These study results strongly indicate that our understanding of severe sepsis is incomplete. Clinical trials of immunomodulatory therapy in severe sepsis have recently been reviewed with the majority showing disappointing outcomes [42]; large clinical studies often contradict the promising preclinical data [43].

## 9 ANTICOAGULANTS

It has long been recognized that inflammation and coagulation are closely linked, and the coagulation system is invariably activated in the presence of inflammation. If uncontrolled, this activation of the coagulation cascade may lead to serious consequences such as disseminated intravascular coagulation or organ failure due to acute vascular events and acute vascular events [44, 45]. Therefore, the understanding and appropriate manipulation of those factor(s) involved in the activation of the coagulation cascade may benefit patients with severe sepsis. To this end, two major coagulation inhibitory factors, anithrombin III and recombinant tissue factor pathway inhibitor (TFPI; tifacogin) were studied in patients with severe sepsis [46, 47]. Again, the results were disappointing [46, 47], contrary to a preliminary study in volunteers, receiving endotoxin followed by TFPI, which showed dose-dependent inhibition of coagulation without influencing the fibrinolytic and cytokine response [48].

## 10 ACTIVATED PROTEIN C

At last in 2001, a recombinant human activated protein C (drotrecogin alfa activated, Xigris) was shown to improve the outcomes of severe sepsis in the single randomized controlled Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) trial [49]. This has led to the approval of DAA in patients with severe sepsis from the U. S. Food and Drug Administration, although by an evenly divided vote. Controversy has followed this drug since then [50–52].

Protein C is activated when thrombin binds the endothelial surface protein thrombomodulin. Activated protein C promotes fibrinolysis and inhibits the generation of thrombin by inactivating factor Va and factor VIIIa [53, 54], and it also has substantial anti-inflammatory properties [55, 56] (Fig. 1). DAA is a recombinant form of human activated protein C and is a serine protease with the same amino acid sequence as human-plasma-derived activated protein C. DAA is a glycoprotein with a molecular weight of approximately 55 kDa, and it has the same site of glycosylation as the human-plasma-derived activated protein C.

The PROWESS study was the pivotal, double-blind, placebo controlled multinational phase III trial of DAA for patients with severe sepsis [49]. In this study, a total of 1690 patients were randomized; 840 in the placebo group and 850 in the DAA group. The baseline patient characteristics including the demography, underlying prior risk factors, APACHE II (Acute Physiology and Chronic Health Evaluation II) scores, and severity scores of the patients in the placebo and treatment groups were well matched.

The trial was originally designed to enroll 2280 patients with two planned interim analyses after 760 and 1520 patients had been enrolled. If the statistical analyses revealed that DAA group was found to be significantly more efficacious than placebo, the guidelines

**Figure 1** Proposed actions of activated protein C in modulating the systemic inflammatory, procoagulant, and fibrinolytic host responses to infection. (Reprinted from [49] with permission.)

**TABLE 1 Summary of PROWESS Trial (Rates of Death from any Cause at 28 Days)**

| Variable | Placebo Group | Drotrecogin Alfa Activated Group | *p* Value | Absolute Reduction in Risk |
|---|---|---|---|---|
| *Treated patients* | | | | |
| Nonstratified analysis | 259/840 (30.8) | 210/850 (24.7) | 0.005 | 6.1 |
| Stratified analysis | | | 0.005 | 6.2 |
| Protein C deficiency | | | | |
| Yes | 215/670 (32.1) | 182/709 (25.7) | 0.009 | 6.4 |
| No | 28/105 (26.7) | 14/90 (15.6) | 0.06 | 11.1 |
| Unknown | 16/65 (24.6) | 14/51 (27.5) | 0.73 | –2.8 |
| *Randomized patients* | | | | |
| Nonstratified analysis | 268/857 (31.3) | 216/871 (24.8) | 0.003 | 6.5 |

were to suspend enrollment. At the time of the second interim analysis of 1520 patients, the difference in mortality rate between the two groups was significant to stop the trial.

In the trial, the treatment group received DAA at a dose of 24 μg per kilogram of body weight per hour, while the placebo group received 0.9% saline with or without 0.1% human serum albumin by continuous intravenous administration at a constant rate for 96 h. The results revealed that the mortality rate of 30.8% in the placebo group and 24.7% in the DAA group (Table 1), for an absolute reduction in the risk of death of 6.1%.

This outcome was accompanied by significantly increased incidence of serious bleeding in the DAA group (3.5%) compared to the placebo group (2.0%). In two patients in the DAA group, fatal intracranial hemorrhage occurred during the infusion period. Although one similar bleed occurred in one subject in the placebo group, it happened 6 days after the end of

infusion. These complications occurred despite very careful exclusion criteria were set forth in advance as described below.

Since DAA has anticoagulant properties, the patients with conditions that increase the risk of bleeding were excluded from the study. These exclusion criteria included were: age ≤18 years; platelet count of ≤30,000; surgery requiring general or spinal anesthesia within 12 h; a history of severe head trauma, intracranial surgery, or stroke within 3 months, intracerebral arteriovenous malformation, cerebral aneurysm, or presence of central nervous system mass lesions; a bleeding diatheses; a history of gastrointestinal bleeding within 6 weeks; a known hypercoagulable state; human immunodeficiency virus infection with cluster of differentiation 4 (CD4) counts of ≤50/mm$^3$; a history of solid organ or bone marrow transplantation; chronic renal failure requiring dialysis; a history of portosystemic hypertension with ascites; acute pancreatitis with no documented infection; and use of anticoagulant including heparin, aspirin, warfarin, and other anticoagulants.

In this study, the patients who received the DAA clearly had benefited with lower mortality due to all causes at 28 days compared to that of the placebo group. This benefit was observed regardless of whether or not the patients had a deficiency of protein C at the baseline, indicating that DAA possesses the additional pharmacologic effect(s) extending beyond the simple replacement of deficient activated protein C [49, 57]. Exact mechanisms underlying the role of DAA in reducing the mortality rate in patients with severe sepsis is unclear. The measurement of two parameters, d-dimer and inferteron-6 levels, during the first 7 days after the initiation of infusion begun, were monitored. The levels of both were significantly reduced in the treatment group, indicating that thrombus formation and the inflammatory process were reduced. Neutralizing antibodies against activated protein C were not detected in any patient, suggesting that the use of DAA may not be associated with antibody-mediated immune complex reactions.

One economic assessment on the entire above patient population that had participated in the trial concluded that the use of DAA in patient with severe sepsis with APACHE II score of 25 or more would be cost effective [58]. Another economic analysis on a similar patient population was not so favorable, although the economic attractiveness improved in patients with high APACHE II (≥25), it was not conclusive and further research needed [53]. It does appear that the use of DAA in patients with severe sepsis and high risk of death (APACHE II score ≥25) is relatively cost effective, but probably not in the lower risk patients (APACHE II score <25).

In the PROWESS study, patients over 75 years old (386 patients), were assessed separately for both short- and long-term survival outcomes [59]. The results revealed that the recipients of DAA had absolute risk reductions in 28-day and in-hospital mortality of 15.5 and 15.6%, respectively, compared with placebo recipients. Long-term follow-up data were available for 375 subjects, and survival rates as analyzed by the 24-month Kaplan–Meier survival curve for DAA recipients showed significantly higher 2-year survival [median 31 days for placebo group vs. 119 days for the DAA group ($p = 0.02$)]. This brings up the question whether or not we should pay special attention to this patient population in the era where the percentage of the population aged ≥65 years is continuously growing [60]. Pharmacokinetics and pharmacodynamics of many pharmacologic agents including DAA, although already being done to some extent with most new pharmacologic agents, should be investigated with special attention to older patients.

In 2005, the study results of adult patients with severe sepsis and a low risk of death, defined as an APACHE II score <25 or single organ failure, were published [61]. This was a randomized, double-blind, placebo-controlled, multicenter, and multinational (516 centers in 34 countries) trial. In this study, a total of 2640 patients were randomized and data from 2613 patients (1297 in placebo group and 1316 in DAA group) were collected. This study was prematurely terminated because of a low likelihood of meeting the statistically significant reduction in the 28-day mortality rate with the use of DAA. The results demonstrated that DAA offered no benefit in mortality rate in low-risk patients, and there was a greater incidence of bleeding (2.4% in the treatment group vs. 1.2% in the placebo group). Therefore, DAA should not be used in patients with severe sepsis with a low risk of death (APACHE II score <25).

In a recent study, only a pediatric population with ages ranging from 34 weeks' gestational age to 17 years with sepsis-induced cardiovascular and respiratory failure was investigated. They were randomized to receive either placebo or DAA (24 μg/kg/h for 96 h) [62]. A total of 477 patients (237 in placebo group and 240 in DAA group) were studied, and there was no significant difference in 28-day mortality rate (placebo 17.5% and DAA 17.2%) between the two groups. Although there was no significant difference in serious bleeding incidences, there were numerically more instances of central nervous system bleeding in DAA group (4.6%) than placebo group (2.1%), especially in children who were younger than 60 days.

An extended safety assessment of the use of DAA in adult patients with severe sepsis has been completed on all available safety data in 6777 patients—2786 patients

who enrolled in phase II and III trial studies, and 3991 patients who received the drug in commercial use [63]. This analysis validated the findings of the major PROWESS study outcome [49].

Based on the above discussion, review of the literature, and review of the package insert [64], the use of DAA in clinical medicine can be summarized as follows:

1. *Indications and Usage* Adult patients with severe sepsis with a high risk of death with an APACHE score >25. DAA is not indicated in patients with severe sepsis with a low risk of death (i.e., APACHE score <25). DAA is not indicated in pediatric patients.
2. *Contraindications* DAA is contraindicated in patients in whom bleeding could be associated with a high risk of mortality and/or morbidity. Conditions belonging to the category may include: active internal bleeding; recent (within 3 months) hemorrhagic stroke; recent (within 2 months) intracranial surgery, or severe head trauma; trauma with an increased risk of life-threatening bleeding; presence of an epidural catheter; intracranial neoplasm or mass lesion or evidence of cerebral herniation; and patients with hypersensitivity to DAA or any component of this product.
3. *Dosage and Administration* DDA should be administered intravenously at an infusion rate of 24 μg/kg infusion rate for a total duration of infusion of 96 h. Dose adjustment based on clinical or laboratory parameters is not recommended. If the infusion is interrupted, DDA should be restarted at the 24 μg/kg infusion rate. Dose escalation or bolus doses of DDA are not recommended. After preparation, the solution should be used at controlled room temperature of 20–25°C (68–77°F) within 12 h.
4. *Warnings* Bleeding is the most common serious adverse effect associated with DAA treatment. Individuals with one or more of the following conditions should be carefully considered prior to the treatment with DAA: patients requiring therapy with heparin for active thrombotic or embolic event; platelet count $<30{,}000 \times 10^6$/L; prothrombin time, international normalized ratio (INR) > 3.0; recent (within 6 weeks) gastrointestinal bleeding; recent (within 3 days) thrombolytic therapy; recent (within 7 days) oral anticoagulants or glycoprotein IIb/IIIa inhibitors; recent (within 7 days) administration of aspirin >650 mg per day; recent (within 3 months) ischemic stroke; intracranial arteriovenous malformation or aneurysm; known bleeding diathesis; chronic hepatic disease; and any other condition in which bleeding constitutes a significant hazard. Should clinically important bleeding occur, stop DAA infusion immediately. Once adequate hemostasis has been achieved, continued use of DAA may be reconsidered. If an invasive procedure that may cause major bleeding planned, DAA infusion should be discontinued 2 h prior to the invasive surgical procedure, and continued use of DAA may be reconsidered 12 h after the procedure.
5. *Precautions* Invasive procedures, including arterial and central venous punctures, should be minimized.
6. *Laboratory Tests* DAA may variably prolong the activated partial thromboplastin time (APTT); therefore, the APTT cannot be reliably used to assess the status of the coagulation during the DAA infusion. However, DAA has minimal effect on the thromboplastin time (PT), and the PT can be monitored to follow the coagulopathy.
7. *Immunogenicity* The incidence of antibody development in patients receiving DAA has not been adequately determined, as the assay sensitivity is inadequate to reliably detect all potential antibody responses. One patient in phase II trial developed antibodies to DAA without clinical sequelae.
8. *Carcinogenesis, Mutagenesis, Impairment of Fertility* Long-term studies in animals to evaluate potential carcinogenicity of DAA has not been performed. DAA is not mutagenic in vitro micronucleus study in mice or in an in vitro chromosomal aberration study in human peripheral blood lymphocytes with or without rat liver metabolic activation. The potential DAA to impair fertility has not been evaluated in male or female animals.
9. *Pregnancy Category C* It is not known whether DAA can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. DAA should be given to pregnant women only if clearly needed.
10. *Nursing Mothers* It is not known whether DAA is excreted in human milk or absorbed systemically after ingestion. A decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

11. *Pediatric Use* A placebo-controlled trial in pediatric patients did not establish the safety and effectiveness of DAA in the pediatric population.
12. *Geriatric Use* No overall differences in safety or effectiveness were observed between these patients and younger patients.
13. *Adverse Reactions* As mentioned above, bleeding is the most common adverse reaction with DAA. In PROWESS study, serious bleeding events were observed during the 28-day study period in 3.5% of DAA-treated patients and 2.0% of placebo-treated patients, respectively. Serious bleeding events included any intracranial hemorrhage, any life-threatening or fatal bleed, and any bleeding event requiring the administration of ≥3 units of packed red blood cells per day for 2 consecutive days, or any bleeding event assessed as a serious adverse event. As described above in the PROWESS study, two cases of intracranial hemorrhage occurred during the infusion period for DAA-treated patients and no cases were reported in the placebo patients. The incidence of intracranial hemorrhage during the 28-day study period was 0.2% for DAA-treated patients and 0.1% for placebo-treated patients. In that study, 25% of the DAA-treated patients and 18% of the placebo-treated patients experienced at least one bleeding event during the 28-day study period. In both treatment groups, the majority of bleeding events were ecchymoses or gastrointestinal tract bleeding. Additional studies with larger patient population were consistent with the PROWESS study findings. Low-dose heparin did not increase the risk of serious bleeding, although the risk of nonserious bleeding was increased compared with placebo over the treatment period of 0–6 days.

## 11 CONCLUSION

Sepsis carries with it a significantly high mortality rate despite tremendous improvements in the understanding of its pathogenesis. Many products designed to interfere with and prevent the sepsis cascade have unfortunately not been found to be helpful, and in some cases have been found to be detrimental. One agent, DAA, has been shown to be beneficial; however, the benefits of this agent is limited to only to a small number of individuals as outlined above. Further research and development of products for the treatment of sepsis must continue if we can try to improve the outcome of this disease state.

## 1 INTRODUCTION

### 1.1 Definitions of Inflammation

Inflammation is the physiological response of the body to injury. In this sense, it serves as a defense mechanism. It is a process typical of vascular tissues, whereby fluid and leukocytes accumulate at the site of injury. The process normally leads to recovery from injury and to healing. However, if targeted destruction and assisted repair are not properly phased, inflammation can lead to persistent tissue damage [1].

*To inflame* means to "set fire." The word comes from *enflamme* in Middle English, *enflamm* in French, and *enflammare* in Latin [2]. In AD 30, Aulus Cornelius Celsus, in his work *De re medica*, recognized what is now known as the four cardinal signs of inflammation: "*rubor et tumor cum calore et dolor*" ("redness and swelling with heat and pain"). Later, a fifth sign, "*functio laesa*" ("disturbed function") was added by Rudolf Virchow, in his *Cellular Pathology* published in 1858. If an organ is inflamed, it does not function as it should. However, beneficial attributes of inflammation were also recognized by the Scottish surgeon-scientist John Hunter. In his 1793 work *Blood, Inflammation, and Gunshot Wounds*, he noted that inflammation is not a disease but rather a "salutary reaction" [3].

For inflammatory diseases, there are clinical needs for anti-inflammatories and analgesics. Simple definitions for these drugs are available. Analgesics are drugs that relieve pain. Anti-inflammatories are drugs used to reduce inflammation—the redness, heat, swelling, and increased blood flow found in infections and in many chronic noninfective diseases such as rheumatoid arthritis and gout.

### 1.2 Importance of Inflammation and Inflammatory Diseases

Inflammation is indispensable to the survival of organisms. Patients with genetic deficiencies in components of the inflammatory process, such as leukocyte adhesion deficiency, have an increased risk of life-threatening infections.

Inflammation serves to rid the body of the source of injury and repair the injured site. However, in situations where such resolution is not possible, for example, during persistent infections, inflammation lingers on and becomes chronic. Whereas acute inflammation only lasts for days, chronic inflammation can last for months and years. Chronic inflammation may be viewed as "frustrated repair." Complete removal of the irritant is essential for repair to progress to completion. Therefore, chronic inflammation is an immune response initiated by an irritant, the persistent antigen [2].

Chronic inflammation contributes to diseases. The connection is more clearly demonstrated in certain diseases. Chronic inflammation has been implicated in arthritis, atherosclerosis, and cancer. In the case for cancer, cellular products of chronic inflammation induce deoxyribonucleic acid (DNA) modifications

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*

leading to somatic mutations that result in carcinogenesis. Therefore, there is demand for anti-inflammatories to treat chronic inflammation and its associated diseases.

### 1.3 History of Anti-inflammatory Therapeutics

The use of salicylate-containing plant extracts has a long history in human civilization. About 2400 years ago, Hippocrates recommended the use of the bark of the willow (*Salix alba*) for the treatment of pain in childbirth. Other plants with similar properties such as meadowsweet (*Spiraea ulmaria*) and wintergreen (*Gautheria procumbens*) have also been used as medicines since antiquity.

Historical development of salicylates is a classic story in the field of pharmacognosy—natural product-derived remedies giving rise to modern pharmacological agents. The development initiated the transformation of the German dye industry into the drug industry in the nineteenth century. A mass-scale chemical manufacture of salicylic acid was made by Frederick von Heyden and Herman Kolbe in 1874. The product was sold as treatment for rheumatism. This commercial endeavor was followed by the development of aspirin.

Because high dose of salicylic acid and sodium salicylate taken by patients led to side effects including nausea, vomiting, and other gastrointestinal symptoms, scientists at Friedrich Bayer and Company were told to synthesize a compound that would be competitively superior to the von Heyden salicylate acid. The young chemist Felix Hoffmann completed the synthesis of acetylsalicylic acid. Hoffman's father had rheumatoid arthritis and found taking several grams of salicylic acid daily unbearable. This synthesis was performed at the suggestion of Hoffmann's supervisor Arthur Eichengrun. The synthesis, previously performed by the French chemist Charles Frederich von Gerhardt in 1853, was the combination of salicylic acid with acetic anhydride to make acetylsalicylic acid.

The product acetylsalicylic acid was introduced as a drug by Bayer in 1899. The director of research at Bayer, Henrich Dreser, did not want the new drug to sound like the old salicylic acid, and named the drug aspirin. The trade name Aspirin came from: "a" for acetyl and "spirin" for natural salicylic acid from plants of the Spiraea family. A less believable version is that the aspirin name was from the early Neapolitan Bishop, St. Aspirinus, patron saint of headaches.

Today, aspirin rates second to alcohol as the most commonly consumed drugs in the world. It has been estimated that 50 billion tablets are taken worldwide annually. Despite intense competition, aspirin is still a well-known, cheap, and effective drug [4, 5]. However, other anti-inflammatory drugs are currently in use, although there is still a genuine need to develop novel agents.

### 1.4 Current Anti-Inflammatory Therapeutics and Their Problems

In 2005, Michael Whitehouse classified the development of anti-inflammatory agents into four types: (1) random discoveries, (2) programmed nonsteroid anti-inflammatory drugs (NSAIDs), (3) synthetic glucocorticosteroids, and (4) biologicals targeting pro-inflammatory cytokines [6]. Examples for random discoveries include the findings of antimicrobials that also relieve the patients' arthritis, such as chloroquine and hydroxychloroquine for malaria treatment, and tetracycline and minocycline for antibacterial treatment. The programmed NSAID development in many drug companies has led to the variety of anti-inflammatory agents currently in use, although some have been withdrawn. Glucocorticosteroid synthesis started with cortisone, followed by hundreds of cortisone analogs. Topical use on the skin and direct inhalation into the lung for asthma patients are examples for anti-inflammatory steroids. Biologicals are the latest products on the market. They are designed to neutralize cytokines or cytokine receptors, especially targeting tumor necrosis factor-α (TNFα) and interleukin-1β (IL-1β). Because biologicals are proteins requiring injections, monitoring, and expensive to manufacture, they cannot be considered as medicine for the masses.

The most common anti-inflammatory therapeutic agents are known as nonsteroid anti-inflammatory drugs. NSAIDs are anti-inflammatory, analgesic, and antipyretic. They act by inhibiting cyclooxygenases (COXs), also known as prostaglandin G/H synthases. The two enzymes are cyclooxygenases 1 and 2 (COX-1 and COX-2). Most NSAIDs act as reversible, competitive COX inhibitors and inhibit both enzymes with little selectivity. NSAIDs are useful in the treatment of rheumatoid arthritis and osteoarthritis. They provide symptomatic relief from pain and inflammation but do not affect disease progression. However, 20% of patients show adverse gastrointestinal side effects.

Among NSAIDs, aspirin is still the most widely consumed anti-inflammatory analgesic, and antipyretic agent and is the standard for comparison and evaluation of other agents. In use since 1893, acetaminophen (trade name Tylenol) is an effective alternative to aspirin as analgesic and antipyretic agent, but it has weak anti-inflammatory effect. Introduced in 1963, indomethacin is used for the treatment of rheumatoid arthritis. It is estimated to be 20 times more potent than aspirin. Indomethacin, in addition to COX inhibition, also inhib-

its leukocyte motility. The compound diclofenic is the most commonly used NSAID in Europe. It has more potent action against COX-2 than indomethacin. Diclofenic is used for long-term symptomatic treatment of rheumatoid arthritis and osteoarthritis. Compared to diclofenic, the most commonly used NSAID in the United States is ibuprofen (trade names Advil, Motrin, Nuprin). It is available without a prescription and used to treat arthritis and other symptoms [7].

The discovery of two COX enzymes and that COX-2 tends to be inducible led to a fashionable but misleading hypothesis that anti-inflammatory effects of NSAIDs might be primarily due to their effects on COX-2, but their principal side effects such as gastrotoxicity might be due to their effects on COX-1, with the corollary to find COX-2 selective agents [6]. These agents are known as COX-1 sparing/COX-2 selective NSAIDs, or "coxibs," and they have become blockbuster drugs.

The COX-2 inhibitor celecoxib (trade name Celebrex), launched in 1998 for indications of inflammatory pain and arthritis, is among the top 10 drugs in global sales, at $4 billion in 2002. On the other hand, another COX-2 inhibitor, rofecoxib (trade name Vioxx), launched in 1999, with $2.16 billion sale in 2000, was withdrawn in 2004 because of increased cardiovascular risk [8]. By inhibiting the COX-2-driven prostacyclin synthesis in the wall of blood vessels but not the COX-1-driven thromboxane-A2 in blood platelets/thrombocytes, the selective COX-2 inhibitor such as rofecoxib causes very serious cardiovascular complications, promoting platelet aggregation and precipitating strokes and many premature deaths. An estimate of a large number of needless deaths (>80,000 by the end of 2004) has been made [6]. The appropriate use of coxibs and NSAIDs has prompted a scientific statement from the American Heart Association to the clinicians [9]. For patients with a prior history of or at high risk for cardiovascular disease, the use of COX-2 inhibitors for pain relief should be limited to patients for whom there are no appropriate alternatives, and then only in the lowest dose and for the shortest duration. The coxibs gained Food and Drug Administration approval based on a superior side effect profile in gastrointestinal endoscopy studies compared with traditional NSAIDs. The problem becomes substituting one side effect for another. Thus, the demand for anti-inflammatory agents remains high, and an urgent need to develop novel therapeutics is warranted.

## 2 IMMUNOBIOLOGY OF INFLAMMATION

Before discussing potential targets for anti-inflammatory therapeutics, we briefly review the inflammatory process, noting the triggers and mediators, as well as the cells and tissues involved in inflammation. (See Fig. 1 for a schematic flowchart of inflammation.)

Inflammation is a complex integrated immune response to cell/tissue injury [10]. Triggered by many types of stimuli (physical, chemical, immunological, or microbial), the process normally initiates the elimination of noxious agent and disposal of damaged tissue in order to promote wound healing. A highly coordinated acute phase is directed toward the site of injury and aims to quickly remove the inflammatory stimulus. During acute inflammation, effector mechanisms of the innate and acquired immune response are activated, and multiple mediators are engaged. Mediators of inflammation vary from small molecules to proteins, and different ones are produced at different phases of inflammation. From plasma, inflammation activates the kinin system to release molecules such as bradykinin, the complement system for molecules such as C3 fragments, and the fibrinolytic system for ones such as fibrinopeptides. Other mediators are produced in cells and tissues. In response to stimulus, effector immune cells, polymorphonuclear neutrophils (PMNs, first line of defense) followed by macrophages, are propagated in increased numbers and recruited to the injured site. The activated macrophage is one main source of inflammation mediators [11]. At the inflamed site macrophages produce mediators that generate the local and systemic symptoms of inflammation [11, 12]. Local acute inflammatory response is demonstrable by the cardinal signs of inflammation, and the phenomenon is characterized by transient vasodilation and increased capillary permeability. The combined efforts of exudate and cells are expected to destroy the inflammatory trigger and restore the injured site of the body.

The local response is accompanied by a systemic reaction known as the acute-phase response. The systemic response is marked by induction of fever in the hypothalamus, increased synthesis of corticosteroids in the adrenal cortex, increased production of leukocytes (leukocytosis) in the bone marrow, and synthesis of acute-phase proteins such as the C-reactive protein in the liver. The systemic response is mediated by the pro-inflammatory cytokines TNF-α, IL-1β, and IL-6 produced by activated macrophages at the site of inflammation.

Whereas PMNs and macrophages are players at early inflammation, at later stages lymphocytes (T and B cells) may participate. Leukocyte trafficking is essential for the inflammatory process. They are transported via the blood vessel, and endothelial cells in the vicinity of the injured site are activated to allow passage of immune cells from blood vessels to the inflamed site [13]. Processes involving chemotaxis, cell adhesion,

**Figure 1** Flowchart of inflammation. Major molecular and cellular events of the inflammatory process are presented in the scheme, with special emphasis on temporal changes at the site of inflammation.

and migration are active in this scenario. During inflammation, additional cells may be involved. In early inflammation, mast cells may produce vasoactive amine histamine. In late inflammation, fibroblasts may produce collagen for tissue remodeling. Ultimately, a successful immune response leads to elimination of stimulus/pathogen and resolution of inflammation [14].

If the initial inflammatory response fails to remove the stimulus/irritant and restore the damage, a chronic proliferative phase sets in. Tissue degeneration and fibrosis may occur. Chronic inflammation is evidenced by disease pathology and may require therapeutic intervention.

## 3 MOLECULAR TARGETS OF ANTI-INFLAMMATORY HERAPEUTICS

A multitude of molecular targets of anti-inflammatory therapeutics are known. The inflammatory stimulus signals the immune cell to activate its kinases (such as mitogen-activated protein kinase p38) and transcription-factors [nuclear factor kappa B (NFκB)], leading to the production of cytokines (IL-1β) and various effective molecules (nitric oxide and prostaglandins) to act at the site of inflammation [15]. For these numerous targets of the inflammatory response, our challenge is to place a value on one target relative to another and to develop strategies to modulate them [16]. Historically, too much

**TABLE 1 Examples of Molecules for the Activation and Resolution of Inflammation**

| Type | Activation | Resolution |
|---|---|---|
| Lipid mediators | Prostaglandins | 15d-$PGJ_2$[a] |
| | Leukotrienes | Lipoxins |
| | PAF | Resolvins |
| | | Protectins |
| Cytokines | TNF-α | TGFβ |

emphasis has been put on monotherapy, treating inflammation with a single agent. With the current knowledge of multiple targets, a judicious combination may be a better approach: particularly when each component is targeted specifically at carefully chosen pro-inflammatory/catabolic proteins, their receptors or their induction mechanisms, perhaps programmed to be used sequentially [6]. Traditional therapeutics have been developed by blocking what initiates and drives inflammation. A novel approach is to design therapeutic agents based on the molecules necessary for the resolution of inflammation [17]. (See Table 1 for examples of molecules for activation and resolution of inflammation.)

### 3.1 Kinases

Reversible phosphorylation via kinase-phosphatase activities, essential for signal transduction, plays a critical role in the inflammatory process. Two kinases in particular have come under scrutiny as potential anti-inflammatory therapeutics.

***Mitogen-Activated Protein Kinase p38 (MAP Kinase p38)*** Originally identified as an enzyme that is phosphorylated and activated by lipopolysaccharide (LPS) in stimulated monocytes, the p38 serine/threonine protein kinase is involved in the synthesis of pro-inflammatory cytokines TNF-α and IL-1β. Four isoforms are known, p38α, p38β, p38γ, and p38δ, with p38α representing a point of convergence of multiple signaling processes during inflammation. This isoform is a potential key target for modulation of cytokine production, and over 100 different inhibitors have been generated [18]. All potent inhibitors are adenosine triphosphate (ATP) competitive and have a significant presence in the adenosine pocket, as seen from the enzyme's crystal structure. The orally active VX702 (Vertex), together with SCIO 469 and SCIO 323 (Johnson & Johnson), are undergoing early clinical trials. AMG 548 (Amgen) and BIRB 796 (Boehringer Ingelheim) will not be developed due to toxicity (elevation of liver enzymes). For a functional inhibitor to be anti-inflammatory, its selectivity over other kinases and the safety issue over long-term use need to be assured.

***Phosphotidylinositol 3-Kinase (PI3K)*** Among the three PI3K classes, the class IB phosphotidylinositol 3-kinase p110γ (PI3Kγ) is another kinase of importance in inflammation. Two isoforms are PI3Kα and PI3Kβ. PI3Kγ, activated by the seven-transmembrane-spanning G-protein-coupled receptors (GPCRs), is the downstream signaling component of a wide range of chemokine receptors. However, it only controls a fraction of the various cellular processes in which it is involved. Therefore, this can yield a "soft" mode of inhibition. Even the most potent inhibitor would only dampen down any given biochemical event. Many inhibitors have been generated, and TG100-115 (3-[2,4-diamino-6-(3-hydroxyphenyl)pteridin-7-yl]phenol), found selective for PI3K in a panel of over 190 kinases, is currently under preclinical development. Although PI3Kγ inhibition has been listed as "an aspirin of the 21st century," the challenge, similar to p38 kinase, is to strike the right balance between isoform selectivity and potency and to combine maximum efficacy with minimum side effects [19].

### 3.2 Transcription Factors

Transcription factors regulate gene expression. The ones implicated in inflammation are nuclear factor kappa B (NFκB), activating protein-1 (AP-1), nuclear factor of activated T cells (NFAT), and signal transduction and activators of transcription (STATs), with NFκB being the most notable [10].

***Nuclear Factor Kappa B*** NFκB is pivotal in the inflammatory response by regulating the expression of pro-inflammatory cytokines, chemokines, adhesion molecules, and inducible enzymes. It also controls the expression of antiapoptotic genes that might protect inflammatory leukocytes from programmed cell death, an important determinant for the resolution of inflammation. The transcription factor works either as hetero- or homodimer, after different combinations of p50, p52, c-Rel, RelA (p65), and RelB subunits. It binds to the DNA sequence known as the κB site and modulates target gene expression. However, under normal conditions, the dimer resides in the cytoplasm in an inactive state by association with the IκB inhibitor proteins.

Upon stimulation (e.g., by the pro-inflammatory cytokine TNF-α), the inhibitor protein is rapidly phosphorylated, ubiquitinated, and then degraded in the proteasome, leaving the activated transcription factor to enter the nucleus. Both phosphorylation and degradation of IκB inhibitor are key steps in the regulation of NFκB, and the IκB kinase (IKK) complex is involved. IKK contains two kinases, IKKα and IKKβ, plus an associated scaffold-like regulatory protein named NFκB essential modulator (NEMO, alias IKKγ). Furthermore, there are multiple pathways for the activation of NFκB, with the classical (canonical) pathway leading to p50/RelA, and the alternative (noncanonical) pathway to p52/RelB [17, 20].

Inhibitors of NFκB have been shown to act at various levels of the complex pathway. Over 750 inhibitors are known, including natural products, chemicals, metals, metabolites, synthetic compounds, peptides, and proteins (from various sources: cellular, viral, bacterial, and fungal). Some are antioxidants, engineered dominant-negative or constitutively active polypeptides, small ribonucleic acid (RNA)/DNA, and even NSAIDs. Aspirin inhibits activation of NFκB in cell culture, although at a higher concentration than the ones used for COXs. Druggable components of the NFκB pathway are actively being pursued, and some are in phase II clinical trials. The aim is to find molecules that block specific pathways leading to NFκB activation without interfering with other signaling cascades, and to discover the ones that can inhibit distinct NFκB complexes induced by select stimuli in specific cell types [21, 22].

### 3.3 Lipid Mediators

Lipid mediators are the most immediate targets of inflammation. The study of eicosanoids (from the Greek *eicosa*, twenty, for 20 carbon fatty acid derivatives) leads to potent eicosanoid lipid mediators prostaglandins and leukotrienes, both derived from the phospholipase-released arachidonic acid. The cyclooxygenases produce prostaglandins and the lipoxygenases produce leukotrienes, both involved in inflammation as well as homeostatic functions of the body. Lipid mediators cause the cardinal signs of inflammation. As an example, prostaglandins elicit increased sensitivity to touch, by sensitizing the free end of pain neurons in peripheral inflammation. Therefore, the lipid mediator pathway of inflammation continues to be a target for the development of anti-inflammatories and analgesics [23, 24].

***Cyclooxygenase (COX)*** Inhibitors of COX-1 and COX-2 are anti-inflammatory agents currently in use. COX-targeting NSAIDs are effective, and aspirin is the most common nonprescription drug. Although COX-2 targeting coxibs have suffered recalls, they nonetheless remain as important therapeutic agents [25, 26]. With careful monitoring of adverse cardiovascular side effects, the COX-2 inhibitors celecoxib (trade name Celebrex, from Pfizer) and parecoxib (trade name Dynastat, from Pfizer) are valuable options for the management of postoperative pain. Parecoxib, the water-soluble prodrug of valdexozib, is the first injectable COX-2-specific inhibitor approved in Europe for short-term treatment of moderate-to-severe postoperative pain [27]. However, because of market removal of rofecoxib (trade name Vioxx, from Merck) and valdezozib (trade name Bextra, from Pfizer) in 2004 and 2005, respectively, future development of anti-inflammatories based on the lipid mediator pathways most likely will be concentrating on other targets.

***Lipoxygenase (LOX)*** Dual-acting anti-inflammatory drugs currently under development are ones that inhibit both cyclooxygenases (COX-1 and COX-2) and 5-lipoxygenase (5-LOX) [28]. The enzyme 5-lipoxygenase (5-LOX) generates leukotrienes, and some leukotrienes are pro-inflammatory. As an example, leukotriene $B_4$ ($LTB_4$) is a potent chemotactic agent that induces chemotaxis of eosinophils, neutrophils, and monocytes to the inflamed site. The classic NSAIDs act by inhibiting the COXs. One of their main drawbacks is the curtailed production of gastroprotective prostaglandins, together with the concurrent increased production of gastro-damaging leukotrienes, because blockage of COX pathways shifts the eicosanoids to the LOX pathway. Dual inhibitors may prevent this from occurring [29]. Licofelone, a balanced dual inhibitor, reduces inflammation in a rabbit model of arthritis [30]. Besides inflammation, dual inhibitors show additional benefits. They are neuroprotective and anticarcinogenic [31].

***Phospholipase (PL)*** Whereas prostaglandins and leukotrienes are targeted by dual inhibitors against COX and LOX, another lipid mediator of inflammation, platelet-activating factor (PAF), a product from lysophospholipid, is still being generated. In order to inhibit PAF, it is necessary to develop inhibitors of phospholipase. Phospholipase $A_2$ ($PLA_2$) catalyzes hydrolysis of phospholipid to generate fatty acid and lysophospholipid. The fatty acid arachidonic acid becomes substrate for COX and LOX, and the lysophospholipid is converted into PAF. Therefore, inhibitors of $PLA_2$ offer the potential to stop the production of a more complete set of inflammatory lipid mediators through the blockade at the onset of the cascade of reactions that follow arachidonic acid release.

A total of 18 human $PLA_2$ are known. Divided into three major classes, the secretory phospholipase $A_2$

group IIA ($sPLA_2$ IIA) becomes the target for anti-inflammatory therapeutics, and many inhibitors have been generated. Whereas animal studies have shown efficacy in models of inflammatory disorders, clinical trials have been less successful. As an example, the potent, selective, and bioavailable $sPLA_2$ IIA inhibitor LY315920 (from Eli Lilly) offered no overall survival benefit to patients with sepsis, although this enzyme is known to be elevated during sepsis. Sepsis is an important medical condition, with estimates of 750,000 episodes annually in the United States, resulting in associated mortality of 30% after 28 days. Other groups of $sPLA_2$, such as group V and X, as well as the cytosolic enzyme ($cPLA_2$) may be compensatory [32]. Further study on this inflammatory drug target is warranted.

***Lipoxins, Resolvins, and Protectins*** Lipoxins, resolvins, and protectins are lipid mediators active at the resolution stage of acute inflammation. Stable analogs of these molecules may be potential anti-inflammatories. Current investigations suggest that the biosynthesis of lipid mediator during acute inflammation is biphasic, with a role for eicosanoids both at the initiation and termination of the inflammatory response, and there is eicosanoid class switching between the two stages [14, 17, 33].

Lipoxins (LXs) and their 15-epimers, aspirin-triggered lipoxins (ATL), are major promoters of resolution of inflammation. Lipoxin is an acronym for lipoxygenase interaction products. First discovered by incubation of human leukocytes with arachidonic acid, they stimulate monocyte recruitment and the uptake of apoptotic PMNs by macrophages and reduce vascular permeability to stop PMN infiltration. Therefore, lipoxins are proposed to act as an endogenous "braking signal" in inflammation; and aspirin jump starts resolution by triggering the biosynthesis of ATL [34, 35].

Besides lipoxins, resolvins and protectins are stereoselective, bioactive, local lipid mediators for the resolution of inflammation. Resolvin is an acronym for resolution-phase interaction products. They are derived from the polyunsaturated fatty acids (PUFAs) eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Protectins and neuroprotectins (protectins generated in neural tissues) are oxygenated products derived from DHA and have anti-inflammatory and neuroprotective actions in animal models. Thus, these molecules possess anti-inflammatory and immunoregulatory activities [14].

Stable analogs of lipoxins, resolvins, and protectins have been chemically synthesized and tested in animal models of inflammation. As an example, the resolvin E1 analog, 19-(*p*-fluorophenoxy)-Rev E1, resists rapid metabolic inactivation and retains bioactivity in reducing PMN infiltration and pro-inflammatory cytokine/chemokine production in vivo [36]. The synthetic stable versions of these proresolving lipid mediators may have clinical applications if proven safe and active.

### 3.4 Receptors

Several groups of receptors are potential targets for anti-inflammatory therapeutics. Cell surface receptors serve to transmit extracellular signals to cellular interior. Different receptors recognize specific signals and act accordingly. For example, both lipoxin $A_4$ and ATL 15-epi-lipoxin $A_4$ act on the G-protein-coupled $A_4$ lipoxin receptor (ALXR, alias FPRL1, or formyl peptide receptor-like 1) [17]. The discovery of hot pepper ingredient capsaicin action on the transient receptor potential vanilloid receptor 1 (TRPV1), a cation channel, opens new horizons in the field of analgesics and pharmacology of norciceptors [37].

***G-Protein-Coupled Receptors*** GPCRs are the most prevalent class of cell surface proteins in pharmaceutical research today. In fact, GPCR-targeting drugs account for one-tenth of worldwide pharmaceutical sales. Of the over 800 GPCRs in the human genome, about 30 have been identified as potential therapeutic targets for the treatment of inflammatory diseases. Examples are receptors for kinins such as bradykinin, complements such as C3a and C5a, and chemokines such IL-8. Nonpeptide ligands that bind peptide-activated GPCRs in inflammation have been produced. Because of their important roles as cellular sentries in inflammatory diseases, GPCRs deserve a great deal more attention as potential therapeutic targets [38].

***Glucocorticoid Receptor (GR)*** Glucocorticoids, cortisol in humans and corticosterone in rodents, are the first examples of endogenous anti-inflammatory molecules, and they have potent anti-inflammatory and immunosuppressive actions. These molecules interact with the receptor, which is a ligand-activated transcription factor. GR acts by masking the DNA-binding domain of other transcription factors such as NFκB, NFAT, AP-1, and STAT. Glucocorticoids are widely used in the clinical control of severe pathologies with an inflammatory etiology, but there are complications due to side effects [39].

Glucocorticoids (GCs) have been historically linked to annexin 1. Originally described as a GC-induced inhibitor of $PLA_2$ and prostaglandin generation in activated macrophages, annexin 1 shares the same receptor as the GPCR $LXA_4$ receptor. Therefore, GC, annexin, and lipoxin are all key players for the resolution of inflammation. Novel GCs with improved specificity

such as the nitro-steroids nitro-prednisolone, and annexino-mimetic, are currently being developed. Thus, the GR pathway provides specific targets for innovative anti-inflammatory drug discovery [40].

***Peroxisome Proliferator-Activated Receptors*** Peroxisome proliferator-activated receptors (PPARs) have strong links with inflammation. Classified into three isotypes, PPARα, PPAR β/δ, and PPARγ, they are ligand-activated transcription factors that act as heterodimer with another transcription factor named retinoid X receptor (RXR). Suppression of inflammation by PPARs has beneficial effects, as shown for the progression of inflammatory diseases in animal models. Currently, several PPAR ligands are in clinical use, notably fibrate for lipid disorder, and rosiglitazone (trade name Avandia, from GlaxoSmithKline) for diabetes. However, the use of PPAR ligands in inflammatory diseases awaits further development [41].

***Toll-Like Receptors*** Toll-like receptors (TLRs) are important in host defense against microbial pathogens. They function as primary sensors of microbial products and activate signaling pathways that induce the expression of immune and pro-inflammatory genes. This pathway must be tightly regulated because the immune system needs to constantly strike a balance between activation and inhibition to avoid detrimental and inappropriate inflammatory responses. Negative regulators of the TLR pathway may lead to novel therapeutic approaches to inflammatory diseases. As an example, the peptide RDP-58 that blocks TLR, is in phase II clinical trial for Crohn's disease [16, 42, 43].

### 3.5 Cytokines

Cytokines continue to be fruitful targets of anti-inflammatory therapeutics. Immune cells produce a diverse range of cytokines serving different functions. Initially, polymorphonuclear neutrophils and macrophages produce the cytokines TNF-α and IL-1β [12]. These pro-inflammatory cytokines are current targets for inflammatory diseases. Later stage cytokines produced by macrophages and T lymphocytes, such as IL-10 and transforming growth factor-β (TGF-β), have important functions in the suppression of inflammation [44–46].

***Tumor Necrosis Factor-α and Interleukin-1β*** TNF-α and IL-1β are situated at the apex of the cascade of inflammation. Therefore, their inhibition is effective for many inflammatory diseases including rheumatoid arthritis [47]. Although therapeutic proteins are expensive to manufacture, all existing agents are proteins. Three anti-TNF-α therapies are available: infliximab (trade name Remicade, from Johnson & Johnson) is a chimeric monoclonal antibody for TNF, etanercept (trade name Enbrel, from Amgen and Wyeth) is a soluble TNF-receptor construct, and adalimumab (trade name Humira, from Abbott) is a human anti-TNF monoclonal [48]. These anti-TNF agents have been touted as the biggest advance in the management of inflammatory arthritis in over 50 years [49]. An anti-IL-1 therapy is available: anakinra (trade name Kineret, from Amgen) is recombinant human IL-1 receptor, antagonist (IL-1RA). IL-1RA acts by binding to the IL-1 receptor, thus blocking the binding of IL-1β to the receptor so as to inhibit signal transduction. While anti-TNF therapy may be more effective, treatments can lead to expression of latent infections, and anti-IL-1 therapy may be preferable under such conditions.

Novel therapies are being developed targeting other cytokines, such as IL-6 and IL-17. Improvement in therapy with regards to cost, efficacy, and tolerability are being made. In addition, there is an urgent need for treatments that are remission inducing rather than just disease suppressing. As an example, in arthritis, disease-modifying antirheumatic drugs (DMARDs) are more attractive than ones merely for the alleviation of symptoms.

### 3.6 Proteinases

Proteinases are appealing targets for development of anti-inflammatories. Cytokines such as TNF-α and IL-1β are synthesized as precursor proteins, and functional cytokines come only after polypeptide processing by proteinases. Furthermore, in inflammatory diseases such as arthritis, proteinases are actively degrading the cartilage collagen proteins. Therefore, modulators of proteinase activity are being investigated.

***Tumor Necrosis Factor-α Converting Enzyme*** Tumor necrosis factor-α converting enzyme (TACE) is a zinc metalloproteinase. The enzyme processes the membrane-bound pro-TNF protein into the released form for circulation. It is postulated that small-molecule inhibitors against TACE will be effective and inexpensive to manufacture. From a medicinal chemistry standpoint, remarkable progress has been made, resulting in the design and synthesis of a large number of potent and differentially selective compounds. These molecules can decrease the level of TNF-α in cell and animal models of inflammatory disease. However, very few end up in clinical trials, with a couple discontinued after phase II, and one (TMI-005 from Wyeth) still in phase I. Concerns over TACE inhibitors include a possible buildup of membrane-bound TNF precursors and their functional

significance, as well as selectivity of the inhibitor toward other metalloproteinases [50].

***Interleukin-1β Converting Enzyme/Caspase-1*** Interleukin-1 converting enzyme (ICE) is a cysteine endoproteinase. Its active form is a heterotetramer, with two p20 and two p10 subunits. The enzyme processes the pro-IL-1 protein into mature functional cytokine that is released into the extracellular environment. Secreted IL-1 binds to IL-1 receptor of the target cell to initiate inflammatory response. Like TACE, small-molecule inhibitors have been sought, and their fate is also similar to TACE. For example, the orally bioactive inhibitor pralnacasan (from Vertex) showed efficacy in phase III trials for rheumatoid arthritis, osteoarthritis, and psoriasis but was discontinued in 2005 due to toxicity. One concern is that the inhibitors may react with other endogenous nucleophiles in the body, leading to toxic side effects associated with long-term use in chronic inflammation [50]. The current nomenclature has renamed ICE as caspase-1.

***Caspases and Inflammasomes*** Caspases are proteinases involved in programmed cell death or apoptosis. Apoptosis is active during the resolution phase of inflammation for the death of polymorphonuclear neutrophils. Inflammatory caspase-1 is activated in a multiprotein complex known as the inflammasome, a structure with associated regulatory proteins and is essential for the processing and secretion of IL-1β. Since current therapies are solely based on neutralization of cytokines that are already in circulation, targeting the inflammasome may prevent their generation and provide a novel approach to anti-inflammatory therapy [51].

***Matrix Metalloproteinases*** TACE is a zinc metalloproteinase, and there are many other metalloproteinases. Originally discovered for the degradation of extracellular matrix such as collagen, they become important enzymes in inflammation and cancer. A nomenclature overhaul changes their names from collagenase, gelatinase, and stromelysin to matrix metalloproteinases (MMPs). Besides the MMPs, there is another group named ADAMs (a disintegrin and metalloproteinases), multidomain metalloproteinases with additional disintegrin domains that are anchored in cell membranes. TACE is a member of ADAMs, alias ADAM-17. A third group is named ADAMTSs (ADAMs with a thrombospondin motif), with aggrecanase as an example. The aim is to develop highly selective and preferentially orally active MMP inhibitors. Unexpectedly, synthetic MMP inhibitors have been disappointing in clinical trials for cancer treatment. However, they may be useful for inflammatory diseases, acknowledging the fact that prolonged clinical application would be necessary for chronic inflammation [52]. For diseases such as arthritis, inhibitor selectivity may be less of a problem because it would be beneficial to inhibit both TACE/ADAM-17 together with other MMPs that degrade the extracellular matrix.

### 3.7 Free Radicals

Free radicals are active in various steps of inflammation. Major ones are reactive oxygen species (ROS) and reactive nitrogen species (RNS). Free radicals target redox-responsive transcription factors such as NFκB [53]. Products of ROS such as hydrogen peroxide have bactericidal properties, and the NADPH oxidase complex from neutrophils is responsible for their production. An important RNS is nitric oxide (NO).

***Nitric Oxide*** NO is produced by the enzyme nitric oxide synthase (NOS). Three known types are endothelial (eNOS), neuronal (nNOS), and inducible (iNOS). NO from iNOS is produced in high-volume output and serves antimicrobial and other functions, including modulation of COX enzymes [54]. The NO free radical was named Molecule of the Year in 1992 by *Science* magazine because of its multiple functions from microbicidal to vessel relaxation (NO was originally named endothelium-derived relaxing factor, or EDRF). However, the use of NO as target of anti-inflammatory can be tricky. The actions of NO in relation to inflammation are multifaceted and as a consequence it remains unclear if NO is pro- or anti-inflammatory; ultimately it is likely to be both, very much dependent on the local concentrations of NO and the prevailing immunological status of the host [55]. Therefore, NO has been described as the "double edge sword mediator," a phenomenon also referred to as the NO paradox. Design of anti-inflammatory therapeutics based on NO must have taken into account this dual nature of NO [56].

### 3.8 Other Targets

Because inflammation is a complex process, it offers ample targets for development of anti-inflammatories. In addition to the ones already mentioned, many others exist. The treatment of multiple sclerosis offers an example. Multiple sclerosis involves inflammation of white matter of the central nervous system, and there is a corresponding animal model, experimental autoimmune encephalomyelitis (EAE). Available current immunotherapeutic potentials of action include: (1) adhesion molecule blockade for specific integrins, (2) cytokines for TNF-α, TGF-β, interferon (IFN), (3) antigen-specific bystander suppression, (4) B-cell

depletion/reduction, (5) chemokine receptor blockade, (6) co-stimulation inhibition for cytotoxic T-lymphocyte-associated protein-4 (CTLA4), (7) depletion/inactivation of pathogenic T cells, (8) Fc-mediated tissue injury/antibody production, (9) general immunosuppression, (10) autologous stem cell rescue, and (11) increase pregnancy-associated hormone signaling [57]. Many of these targets are common to other inflammatory diseases; several targets are further discussed below.

***Chemokines*** Leukocyte trafficking is a continuous process during inflammation. Thus, adhesion molecules, chemotactic molecules, or chemokines and chemokine receptors are valuable targets for anti-inflammatories [58].

***Heat Shock Proteins*** Heat shock proteins (HSPs) are cellular stress proteins and their synthesis is upregulated during stress, including inflammation. Acting as molecular chaperones, they have paradoxical effects toward cell injury. HSP induction before a pro-inflammatory stimulus is beneficial but HSP induction after a pro-inflammatory stimulus is cytotoxic. They are abundant intracellular proteins and are also very immunogenic. In addition, specific TLRs may serve as HSP receptors. Modulating HSP levels and their receptors may be potential drug targets in inflammation [59, 60].

***More Proteins, Peptides, and Other Molecules*** At the early stage of inflammation, there is activation of the complement system. The products C3a and C5a are known as anaphylatoxins and are potent pro-inflammatory mediators [61]. Complement components are targets of anti-inflammatories. The pro-inflammatory cytokines include interleukin-1β. IL-1β binds to its receptor, and this is followed by receptor clustering into a multiprotein aggregate known as a cell adhesion complex. Blocking this process with peptides is another novel anti-inflammatory strategy [62]. The suppressor of cytokine signaling (SOCS) proteins regulate cytokines. Their use for suppressing cytokine signaling may be therapy for the treatment of inflammatory diseases [63]. In specific diseases such as arthritis, loss of cartilage and bone can occur. Under such conditions bone morphogenetic proteins (BMPs) may be applicable for repair [64]. In neuroinflammation, neuropeptide Y (NYY) and related peptides may have a role in clinical application [65]. Moving from proteins to carbohydrates, hyaluronan (HA), the long-chain polysaccharide composed of repeats of disaccharide units of glucuronic acid and *N*-acetylglucosamine as a component of extracellular matrix, seems to have a role in modulating inflammation. Interestingly, the effect is dependent on molecular size, with larger polysaccharide chains having anti-inflammatory activity and smaller ones having pro-inflammatory properties. This knowledge may assist investigators to harness the beneficial effects of HA in anti-inflammatory therapeutics [66].

## 4 EXPERIMENTAL METHODS FOR IDENTIFYING ANTI-INFLAMMATORIES

From in vitro cultured cell assays to in vivo animal models, various experimental approaches are available for the development of anti-inflammatory therapeutics. The benefits and limitations of these tools must be recognized, so the investigator can make an informed decision in choosing the most appropriate experimental system.

### 4.1 In Vitro Assays of Inflammation

In vitro assays are mostly based on cell cultures. They are attractive because experiments are fast and economical. The assays are relatively easy to perform, and many are also amendable to high-throughput formats (for mass screening). From the standpoint of anti-inflammatory therapeutics, activity of proteins and enzymes can be tested using cell lysates or recombinant proteins. Monocytes and macrophages are central in the inflammatory response, and rodent and human cell lines are readily available. In addition, normal, unstimulated monocytes/macrophages can be obtained from blood samples of human volunteers and from the mouse peritoneum. For example, we have used the human cell line MonoMac 6 to demonstrate the inhibition of NFκB activation by the phytochemical curcumin using the electrophoretic mobility shift assay (EMSA) [67]. However, EMSA is a cumbersome assay. A commercially available alternative is to test the activated transcription factor by an enzyme-linked immunosorbent assay (ELISA)-based nuclear binding assay, utilizing immobilized κB-specific oligonucleotide and nuclear lysates. In addition, other assays such as IκB kinase activity are available for the NFκB signaling pathway. To check the inhibition of transcription-factor-dependent gene expression, NFκB response element sequence can be linked to a reporter gene such as the firefly luciferase, yielding an easy and highly sensitive luminescence assay [68].

Assays should be selected depending on the targets of inflammation. For example, to test the secretion of lipid mediators and cytokines by immune cells, ELISA method for specific prostaglandins or cytokines can be used. Fluorescence-based immunoassays measuring multiple cytokines from single samples (multiplexing) are also available. Different cell types are appropriate

for specific purposes, for example, endothelial cells for adhesion molecule expression and macrophages for phagocytosis. We have isolated murine peritoneal exudate cells (macrophages) and showed that iNOS activity (stimulating the cells with lipopolysaccharide and interferon γ and testing NO production with Griess reagent) can be inhibited by phytochemicals [69]. Arthritis is an important inflammatory disease. Proteinases such as MMPs can be assayed with various peptide substrates that allow sensitive fluorometric detection. In vitro model of cartilage degradation is possible, by incubating isolated human and calf cartilage with cytokines such as IL-1β, and checking for the released degradation products hydroxyproline and glycosaminoglycan in culture medium. Potential inhibitors of cartilage breakdown can be added to monitor their effects [68].

### 4.2 In Vivo Models of Inflammation

In vivo models of inflammation involve laboratory animals. The process to assay potential anti-inflammatories normally progresses from in vitro to in vivo because it is often difficult to predict inhibitory potency and selectivity obtained from in vitro experiments for clinical usefulness. Additional concerns are delivery and bioavailability: how to send the therapeutic agent to the site of inflammation and how to prevent its modification and degradation by the body's metabolism of xenobiotics. For in vivo works, animal welfare is an increasingly significant issue. Regulations on this subject vary by country. In the United States, approval for animal protocols must be obtained from the Institutional Animal Care and Use Committee (IACUC) before initiating any experimentation [70].

Many animal models are available for testing anti-inflammatories in vivo. Rats and mice are more economical, but guinea pigs, rabbits, and dogs have established models for diseases such as arthritis [68, 70]. Rats and mice are rodents, with rats being larger in size for sampling and analysis, and mice demonstrating the advantage of genetics (from inbred strains to transgenic and knockout animals). For example, we have used a murine sepsis model by injecting lipopolysaccharide into animals to show in vivo effect of the phytochemical curcumin [71]. For studies on potential therapeutics for arthritis, a useful model is rodent collagen-induced arthritis (CIA). We first inject chicken collagen (type II) and adjuvant to the DBA strain of mice. CIA is then followed for several weeks by measuring the increase in paw thickness and the changes in inflammatory state by histology [70].

With the abundance of animal models for anti-inflammatory research, some more costly than others, judicious choice for the ones to be used should be based on specific objectives. An example for a simple model is carrageenan-induced rat paw edema (CPE), a test that can be completed in less than a day. CPE is involved in the launching of indomethacin, although delayed response of fibrosis has been neglected [6]. Another quick assay is acute inflammation of rodent ears after stimulants such as tetradecanoylphorbol acetate (TPA). A third model is the air-pouch: in 1953, Hans Selye originally described that injection of air into the dorsal surface of rats provides a cavity in which the inflammatory response can be studied. The model allows performance of biochemical analysis of both the exudate and inflammatory cells, together with histological analysis of the air-pouch lining. Modifications such as the murine carrageenan air pouch and the chronic granulomatous air pouch have been reported [68].

Specific animal models are available for different inflammatory diseases, such as asthma, skin and neuro-inflammation, and inflammatory bowel disease (IBD) [72]. For IBD, there are models using hamsters and mice by feeding dextran sulfate sodium (DSS solution) to animals to induce colitis, with treatment for 5 days for acute and 21 days for chronic colitis. The hypothesis is that DSS converts to hydrogen sulfide, which is toxic to gut epithelium.

A general strategy for testing anti-inflammatory therapeutics proceeds from cells to animal studies. However, for potential therapeutics such as phytochemicals already in use, a jump from in vitro assays to humans is possible. Hops (used in beer brewing) are a useful example. Screening of phytochemicals in vitro against COXs in cell lines generated potential therapeutics (using ibuprofen as positive control); testing in human volunteers leads to the conclusion that a hops extract may be useful as anti-inflammatory dietary supplement [73].

We end this section with a word of caution: Potential anti-inflammatories may not work in a specific animal model. For example, chloroquine and minocycline (currently in use for arthritis) are inactive in rodent arthritis models [6]. Shortfall of each animal model must be recognized. If the budget permits, multiple experimental models should be used so as to complement each other.

## 5 PIPELINE NOVEL ANTI-INFLAMMATORIES

For anti-inflammatory therapeutics, what comes next? Many compounds have been tested but then withdrawn at different stages of development. A bright spot for the immediate future will be the nitric-oxide-releasing non-steroid anti-inflammatory drugs (NO-NSAIDs). This is

a new class of anti-inflammatory and analgesic drugs, generated by adding nitroxybutyl or nitrosothiol moiety to the parent NSAID via a short-chain ester linkage. Two compounds, NO-aspirin and NO-naproxen, are undergoing phase III clinical trials [74]. Effectiveness has already been assessed in vitro, in vivo, and in human volunteers. NO released from NO-naproxen inhibits both COX-1 and COX-2 in cell cultures in vitro [75]. In animal models, NO-diclofenac works in carrageenan-induced paw edema, and NO-naproxan in rat adjuvant-induced arthritis, although potential activation of cartilage metabolism by NO is a concern that needs to be addressed [56, 76]. In human trials, NO-aspirin spares the gastric mucosa while inhibiting platelet aggregation and allowing the production of aspirin-triggered lipoxin (ATL) [77, 78]. Thus, the combination of balanced inhibition of COX-1 and COX-2 with the release of NO confers to NO-NSAIDs a reduction in gastrointestinal and cardiorenal toxicity. These NO-NSAIDs have been renamed; now they are known as cyclooxygenase inhibitor NO donors (CINODs) [74].

A footnote can be added to the CINOD discussion. Adding NO to other anti-inflammatory therapeutics has been achieved, such as the NO-releasing steroids NO-prednosolone [40]. Hydrogen sulfide ($H_2S$) can be used instead of NO because it also modulates inflammation at physiological concentration. The $H_2S$ donors increase resistance of the gastric mucosa to injury and accelerate repair. Hence $H_2S$-releasing NSAIDs, such $H_2S$-releasing derivatives of indomethacin and diclofenac, are being investigated [79].

## 6 NATURAL ANTI-INFLAMMATORY COMPOUNDS IN FOODS AS DIETARY THERAPEUTICS

Natural products have played an essential role in drug discovery. Recent examples are lovastatin for cholesterol lowering, artemisinin for malaria, and paclitaxel for cancer [80]. Starting from the story of willow bark leading to aspirin, phytochemicals commonly have anti-inflammatory activity. A total of 38 plant species has been identified in a review on patented anti-inflammatory plant drug development, with the botanicals showing diverse chemical structures, polysaccharides, terpenes, curcuminoids, alkaloids, and many others [81]. A proprietary avocado soybean product has been reported to be effective in the treatment of painful osteoarthritis and chronic lower back pain [82]. A future anti-inflammatory drug for rheumatoid arthritis and other diseases may come from the Chinese herb, *Tripterygium wilfordii*, locally known as "thunder god vine." Its terpene triptolide and other metabolites act on inflammation targets such as COX-2, TNF-α, iNOS, and NFκB [83].

Whereas phytochemicals continue to yield products with anti-inflammatory therapeutics, the variety of fruits, vegetables, beverages, meat, seafood, and spices consumed by the individual also contains compounds with such properties. These food-derived molecules have GRAS (generally regarded as safe) status. One group, collectively known as dietary polyphenols, has anti-inflammatory properties targeting transcription factors such as NFκB, enzymes such as iNOS and COX, as well as acting as antioxidants [84–87]. Examples are resveratrol, epigallocatechin 3-gallate, and curcumin. Another group, also associated with inflammation, is the omega-3 fatty acids. These compounds are discussed here as dietary therapeutics. (See Fig. 2 for their chemical structure.)

**Figure 2** Selected dietary compounds with anti-inflammatory properties. From top to bottom, the molecules shown are the omega-3 polyunsaturated fatty acids EPA and DHA, followed by the polyphenols resveratrol, EGCG, and curcumin.

### 6.1 Omega-3-Polyunsaturated Fatty Acids

Omega-3-polyunsaturated fatty acids (ω-3 PUFAs), including eicosapentaenoic acid (EPA) (20:5ω-3) and docosahexaenoic acid (DHA) (22:6ω-3), come from oily marine fish in the diet (or fish oil supplements). The typical fish oil may contain 18% EPA and 12% DHA. At doses of milligrams to grams per day, PUFAs show beneficial actions in many diseases, including inflammatory diseases [14, 88, 89]. Possible mechanisms on inflammation relief include competing with arachidonic acid to decrease the production of inflammatory eicosanoids and acting as substrates for the synthesis of the anti-inflammatory lipid mediators such as resolvins and protectins. Although in vitro and animal studies have demonstrated anti-inflammatory activity, the evidence from human trials is somewhat equivocal [90]. The cause may be genetic variation, differences in individual responsiveness to nutrient modulation of inflammation. Another reason may be appropriateness of the selected assay. Condition-specific clinical endpoints may be more sensitive markers of modulation by EPA and DHA than cytokines [91]. For clinical studies, a meta-analysis has concluded that PUFAs have analgesic effects for inflammatory joint pain, and another review of diet and rheumatoid arthritis also concluded that dietary supplementation with PUFAs can provide modest symptomatic benefit in patients with rheumatoid arthritis [92, 93]. Thus, a diet of marine fish may be beneficial to individuals with inflammatory diseases.

### 6.2 Resveratrol

Resveratrol comes from grapes, peanuts, pine nuts, and red wine in the diet. The molecule is known as a phytoalexin, the compound produced by plants against pathogen attack. We have shown that resveratrol is active against human dermal fungal pathogens and may be useful for treating athlete's foot [94]. This polyphenol has multiple health benefits, especially cardioprotection. It acts on the enzyme sirtuin deacetylase and can extend life spans of yeasts, nematodes, fruit flies, and fish [95, 96]. Resveratrol also shows anti-inflammatory activity. It downregulates the inflammatory response by targeting molecules such as COX and NFκB, and this activity may be the basis of its cardioprotective effect [97]. A phenomenon known as the "French paradox" refers to the French who enjoy a relatively low risk of cardiovascular disease despite a diet high in saturated fat; resveratrol and alcohol in red wine may be part of the reason [98]. Thus, a diet including red wine may be beneficial to individuals with cardiovascular and inflammatory diseases.

### 6.3 Epigallocatechin 3-Gallate

Epigallocatechin 3-gallate (EGCG) comes from green tea in the diet. Made from leaves of the plant *Camellia sinensis*, tea is the most popular beverage consumed in the world, second only to water. Approximately 20% of the world's tea is consumed as green tea, and 78% as black tea. EGCG is the major green tea polyphenol, accounting for 30–40% dry weight of the water-extractable material of green tea. It is converted to dimers and polymers during the production of black tea. EGCG has multiple health benefits, including cancer chemoprevention and anti-inflammatory activity. It acts on multiple cellular targets, from enzymes to signaling pathways [99–102]. We have shown its inhibition of iNOS at both gene expression and enzyme activity levels [103], and EGCG acts synergistically with the chemotherapeutic compound cisplatin to kill drug-resistant cancer cells [104]. Others have shown EGCG inhibition of MMPs [105], and green tea polyphenol prevents the onset of murine collagen-induced arthritis [106]. EGCG, like resveratrol, is antimicrobial, and may be useful in preventing dental caries (green tea polyphenol in toothpaste). Thus, a diet including green tea may be beneficial to individuals for cancer prevention and inflammatory diseases.

### 6.4 Curcumin

Curcumin comes from the spice turmeric in the diet. Turmeric is produced from rhizome of the plant *Curcuma longa*. Curcumin is also responsible for the yellow color of curry spice mix. Besides its use as spice, turmeric has been applied in traditional Asian Indian medicine from treating insect bites to wound healing. The polyphenol curcumin is the major compound of turmeric. Multiple and diverse bioactivities have been attributed to curcumin, including anti-inflammatory activity. It acts on targets such as COX, LOX, iNOS, NFκB, AP-1, and many others [107–111]. We have shown its inhibition of NFκB in vitro and its inhibition of iNOS in liver and spleen in a murine sepsis model in vivo [67, 71]. Thus, a diet including curry dishes may be beneficial to individuals for cancer prevention and inflammatory diseases.

As discussed above, omega-3 unsaturated fatty acids, resveratrol, epigallocatechin 3-gallate, and curcumin are dietary ingredients with experimental data demonstrating anti-inflammatory activities. This is an evidence-based approach toward dietary compounds, although a major concern is whether their disease-modifying level is achievable in the body [112]. The effects of diet on inflammation have been analyzed. Specific dietary

patterns, such as the Mediterranean diet, because of anti-inflammatory properties, are known as protective against cardiovascular disease [113]. It has been suggested that western dietary patterns warm up inflammation, while other dietary patterns may cool it down [114]. For specific diseases such as arthritis, a large number of inexpensive natural products that can modulate inflammatory responses, but lack side effects, constitute "gold mines" for disease treatment [115]. Hence we propose the idea of natural anti-inflammatory compounds in foods as dietary therapeutics.

## 7 FUTURE PROSPECTS

The development of anti-inflammatory therapeutics is an active area of pharmacological research. As we look forward to future discoveries, it also pays to look to the past for potentially useful but neglected therapeutic agents.

Older compounds may still be worthwhile for consideration as anti-inflammatories. One example is thalidomide, the drug that had caused a birth defect disaster. Another is cannabinoid, the molecule that has been associated with substance abuse. Alternatively, current drugs may have novel applications as anti-inflammatories. One example is the statins [116]. Some anti-inflammatories may be underutilized, such as the less toxic but slow-acting antimalarials. This may be due to patent expiration that caused the compounds to lose drug company sponsors [6].

Targets for anti-inflammatory therapeutics have been and will be discovered. We give two examples. Suberoylanilide hydroxamic acid (SAHA), the histone deacetylase inhibitor, prevents collagen-induced arthritis in rodents, thus suggesting an innovative therapeutic strategy for rheumatoid arthritis [117]. Polymorphonuclear neutrophils and macrophages produce catecholamines upon stimulation by lipopolysaccharide. As catecholamines enhance inflammatiory injury, discovery of this previously unrecognized source allows development of novel anti-inflammatory strategy (namely $\alpha_2$-adrenoreceptor blockade) [118]. Bringing initial observations to final therapeutic drugs takes judgment, luck, time, and effort, and we look forward to industrial and academic pharmacologists to achieve this goal.

## ACKNOWLEDGMENT

We thank Cara Nasello and Marisa Apicella for helpful comments. The writing of this chapter was supported, in part, by a grant from the National Institutes of Health (5R21AR051761-02) to Marion Chan, and a grant from the Department of Defense (DOD-W911QY-07-C-0007) to Marion Chan and Dunne Fong.

## 1 INTRODUCTION

### 1.1 Inflammatory Response and Inflammatory Pain

Inflammation in mammals is a complex biological response to the endogenous or exogenous products of injury or infection (danger signals), for example, pathogens, damaged cells, and inflammatory mediators. Cells in the immune system are equipped with receptors for these stimuli; notable examples are the interleukin-1 (IL-1), tumor necrosis factor-α (TNF-α), and Toll-like receptors. The cells in the innate branch of the immune response such as neutrophils, epithelial cells, and monocytes/macrophages are the first responders to such danger signals. Receptor ligation on these cells induces an acute cellular response that is characterized by the expression of a repertoire of early-response genes including genes that encode for pro-inflammatory cytokines (TNF-α, IL-6), chemokines (IL-8, Gro-α/CXCL1) and antibacterial agents (antimicrobial peptides, reactive oxygen/nitrogen species). The mediators that are produced from early-response gene transcription will prompt additional cellular and physiological events that collectively facilitate eradication of the irritant that initiated the response [1]. In doing so, however, the inflammatory mediators inescabably cause collateral damage to host tissues and can stimulate inflammatory and neuropathic pain [2]. Inflammatory pain is associated with swelling and damage in the inflected tissue via the natural influx of immune cells and subsequent release of proteases and toxic agents. Neuropathic pain results from the activation and sensitization of primary sensory nociceptors in the peripheral nervous system (PNS) and/or via dorsal horn and brain neurons in the central nervous system (CNS). Mediators of both peripheral and central sensitization to pain include prostaglandins, nitric oxide (NO), and cytokines (TNF-α and IL-1β). To minimize the negative effects that can be incurred during an inflammatory response, the process is designed to be inherently self-limiting. Receptor ligation inevitably induces an active anti-inflammatory response through the production of anti-inflammatory mediators [e.g., IL-10, transforming growth factor-β (TGFβ)] and the expression and/or activation of cellular proteins that calm the cellular response to stimuli. This culminates in physiological processes such as wound healing and a reversion to basal levels of cellular activity in which pro-inflammatory responses are constrained by negative regulation. As both inflammatory and neuropathic pain are linked to the inflammatory episode, sensations of pain should cease with the resolution of the inflammatory response.

The coordinated induction and resolution of the inflammatory response is a complex system that depends on the balanced expression and management of numerous positive and negative regulatory molecules. The family of mitogen-activated protein (MAP) kinases are key signaling molecules broadly expressed in cells and tissues of the immune system. MAP kinases profoundly influence many aspects of cellular physiology via regulation of gene transcription, protein synthesis, cell-cycle

regulation, cell death, and differentiation [1]. It is well established that MAP kinases along with the transcription factor nuclear factor κ B (NFκB) promote and coordinate the expression of inflammatory mediators. MAP kinases have also been implicated in the regulation of inflammatory and neuropathic pain. Signals mediated by MAP kinases and NFκB are under strict control to ensure that any activation is both timely and appropriate in magnitude and duration. A collapse of the regulatory measures either in the presence or absence of an obvious initiating stimulus can lead to some of the most serious threats to human health, including long-term pain, chronic inflammatory diseases, and endotoxic shock [3]. Millions of people worldwide suffer from chronic inflammatory diseases and pain. More than 2 million people in the United States alone suffer from the inflammatory disease rheumatoid arthritis (RA). This disease is characterized by pain, swelling, and stiffness in the joints that is driven by the overproduction of inflammatory mediators including those that are influenced by MAP kinases (MAPK).

Steroidal and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most efficacious treatments currently available for inflammation and inflammatory pain. NSAIDs inhibit cycloxygenase (COX) to prevent the production of prostaglandins that mediate inflammatory and anaphylactic reactions. Steroidal drugs such as corticosteroids and glucocorticoids inhibit the transcription of inflammatory genes. The mechanism of their action is not fully understood, but evidence suggests that glucocorticoid receptor-mediated signaling can suppress MAPK activity, thereby inhibiting gene transcription [4–6]. While these treatments may be highly effective, they are also expensive, and, of greater concern, they can cause dire side effects. The advent of COX-2-selective NSAIDs have reduced but not eliminated the significant risk of mortality associated with earlier NSAID compounds. Immune surveillance and cell-mediated immunity can be significantly compromised in patients receiving glucocorticoid thereapy as critical cytokines that drive B- and T-cell proliferation, lymphocyte function, and $F_c$ receptor expression are not transcribed. Glucocorticoids have also been known to cause adrenal insufficiency, osteoporosis, inhibited growth, decreased skin resiliency, and hyperglycemia. Thus there is a considerable need to develop new anti-inflammatory and antianalgesic therapies that are efficacious, selective, and economically viable.

### 1.2 Protein Kinases

Protein kinases are enzymes that catalyze the transfer of phosphate from adenosine triphosphate (ATP) to a hydroxyl side chain on serine, threonine, or tyrosine residues within a protein. The phosphorylation reaction is reversed by enzymes in the corresponding family of protein phosphatases. Together kinases and phosphatases regulate the phosphorylation state of cellular proteins that can control various aspects of protein structure and function, for example, cellular localization, interaction partners, stability, and enzymatic activity. It has been estimated that phosphoproteins comprise one-third of all cellular proteins. Protein phosphorylation is a common aspect of cellular signal transduction that is integral to the maintenance of normal cell physiology and responsiveness to environmental (extracellular) cues. The transmission of an extracellular signal via a protein phosphorylation network often evokes gene transcription and a cellular response to the original input.

The introduction of deoxyribonucleic acid (DNA) cloning and sequencing in the 1970s and the discovery that protein kinases have a high degree of sequence similarity in the catalytic domain enabled the identification of nearly 100 protein kinases by the mid-1980s [7]. At that time, it was speculated that the human genome was comprised of 50,000–100,000 genes, and Hunter et al. predicted that as many as 1000 of these genes, or 1–2% of the entire genome, coded for protein kinases. The first published sequence of the entire human genome came a mere 15 year later [8], which facilitated a genetic analysis of gene families involved in cellular phosphorylation events and the construction of the human "kinome," a compilation of the full complement of protein kinase genes [9]. Consistent with the original prediction, 1.7% of the human genome (518 genes) codes for protein kinases, making this one of the largest families of genes [9].

### 1.3 MAP Kinases

The family of MAP kinases (EC 2.7.11.24) are proline-directed serine/threonine-specific kinases. MAPKs are part of a phosphorylation signaling cascade that is activated in response to extracellular stimuli, primarily cytokines and environmental stress. Central to classic MAPK signaling cascades is a three-tiered hierarchical module of serine/threonine and dual-specificity protein kinases (Fig. 1). MAP kinase kinase kinases (MKKK or MAP3K) form the first tier in the MAPK cascade. Stimuli-induced MAP3K phosphorylate serine and threonine residues on downstream dual-specificity MAP kinase kinases (MKK, MAP2K or MEK). In turn, the phosphorylated MAP2Ks activate MAPK through phosphorylation on threonine and tyrosine residues. The family of MAP kinases and the MAPK phosphorylation cascades have been well conserved in evolution. The mammalian MAPK family can be subdivided into

**Figure 1** Generic MAPK signal transduction cascade.

distinct groups, four of which have been extensively characterized: extracellular signal-regulated kinase 1, 2 and 5 (ERK1, ERK2, ERK5), c-Jun N-terminal kinase (JNK), and p38. The MAP kinases ERK3, ERK4, ERK7, and ERK8 are structurally related, atypical MAP kinases with distinct regulation and function compared to the other ERK family members. The ERK and JNK MAP kinases are described briefly below as well as in Table 1 and Figure 2. The reader is encouraged to refer to several recent reviews on MAP kinases for a more comprehensive discussion [10–12].

***ERK1/2*** In 1991, extracellular signal-regulated kinase-1 and -2 (ERK1, ERK2) were the first MAPK family members discovered; thus ERK1/2 are considered the prototypic MAP kinases [13]. ERK1 and ERK2 are 44 and 42 kDa, respectively, with 90% sequence identity. ERK1/2 are preferentially activated by growth factors and phorbol esters (tumor promoters), regulate cell proliferation and differentiation, and are therapeutic targets in cancer [14].

***ERK5*** While this kinase shares ~66% sequence identity with ERK1/2, it is significantly larger (98 kDa) [15]. Fittingly, it was also ascribed the name Big MAP kinase-1 (BMK1). Three isoforms of the protein exist, two of which may act in a dominant-negative fashion. With the exception of the liver, ERK5 is ubiquitously expressed and is responsive to growth factors, oxidative stress, and mitogenic stimuli [16, 17].

***ERK3/4*** ERK1/2 and ERK3/4 differ in the C-terminus (which is longer in ERK3/4) and in the highly conserved activation loop that is found between kinase subdomains VII and VIII. ERK3/4 are the only MAPK family members to contain a Ser-Glu-Gly motif instead of the characteristic Thr-Glu-Tyr motif, which is dually phosphorylated on the threonine and tyrosine residues. Consequently, ERK3/4 are not substrates for the same kinases that phosphorylate and regulate ERK1/2 [17, 18].

***ERK7/8*** ERK7 and ERK8 share approximately 82% amino acid identity in the kinase domain and 40% homology with ERK1/2. Like ERK3/4, ERK7/8 differ from ERK1/2 in the C-terminus and do not appear to be substrates of typical ERK1/2-activating kinases [17].

***JNK/SAPK*** Stress-activated protein kinases (SAPKs), also known as c-Jun N-terminal kinases (JNK), are responsive to stress stimuli such as cytokines, ultraviolet (UV) irradiation, heat shock, and osmotic shock. JNK1 and JNK2 are ubiquitously expressed while JNK3 expression is limited to the brain, heart, and testis. Differential splicing within the catalytic domain and C-terminus of JNK1-3 can create at least 10 isoforms of JNK. Biological roles for JNK have been linked to cellular apoptosis, cellular differentiation, and embryogenesis [19, 20].

The genuine in vivo function(s) of many MAP kinases in cellular and biological processes and disease pathogenesis remain elusive [10]. Difficulties arise in part from functional redundancy within the MAPK family and a high degree of interconnectivity with other signal transduction cascades. Mice deficient in a single MAPK are often either phenotypically indistinguishable from wild-type mice (e.g., ERK2, JNK3, and p38β,δ,γ isoforms) or not viable (e.g., ERK2, ERK5, and p38α isoform). While this outcome established a role for certain MAP kinases in development [21], it prevented an analysis of the role(s) of these kinases in mature animals [22].

## 2 P38 MAP KINASE FAMILY

### 2.1 Discovery

The p38 MAPK family is highly conserved throughout evolution with mammalian homologs existing in yeast (Hog1 and Spc/Sty1), worm (pmk1-3), fruit fly (D-p38a/Mpk2, D-p38b), and frog (Mapk14a) [23–25]. Like JNK, p38 MAP kinases respond to stress stimuli and are implicated in cell survival, growth, differentiation, and apoptosis [14, 20]. Four isoforms of p38 (p38α, p38β, p38γ, and p38δ) have been discovered in mammals, the first of which, p38α, was described independently by several investigators in 1994 in the context of cellular responses to stress. Lee and colleagues at SmithKline & French discovered p38α as the molecular target responsible for the inhibition of TNF-α production in lipopolysaccharide (LPS)-stimulated monocytes treated with a cytokine suppressant anti-inflammatory drug (CSAID). Aptly, p38 was named a CSAID-binding protein (CSBP) [26]. Han et al. described a 38-kDa tyrosine phosphorylated polypeptide in human monocytes subjected to endotoxin and hyperosmolarity shock [27, 28]. Finally, two laboratories independently discovered that p38 [named p40 and reactivating kinase (RK)] regulated MAPK-activated protein kinase-2 (MAPKAPK2) and, in turn, heat shock protein 27 (hsp27) in response to stress [29–32]. The isoforms p38β, p38γ, and p38δ were

identified a few years after the discovery of p38α through expressed sequence tag (EST) database analysis and homology screening [33–38].

Two splice variants of p38α have also been described. The potential splice variant Mxi2 was identified by association with the transcription factor max and the C-terminus of c-myc in a yeast-2-hybrid screen. While the ATP-binding pocket and activation loop are conserved, Mxi2 lacks 65 amino acids at the C-terminus, is less sensitive to inhibition by CSAID, and does not have activators and substrates in common with p38α [39, 40]. Exon-Skp (Exip) binds to the IL-1R/Toll-like receptor (TLR)-associated signaling molecules Tollip (toll interacting protein) and IRAK (interleukin-1 receptor-associated kinase), and overexpression of Exip marginally impaired IL-1β-induced activation of NFκB [41, 42]. The functional relevance of these splice variants has not been elucidated.

### 2.2 Distribution

The p38α, β, and δ isoforms are widely expressed, although not to equivalent levels, whereas the expression of p38γ is restricted to skeletal muscle. p38α is highly expressed in human lymphoid tissues (spleen, lymph node) and in peripheral leukocytes, most prominently in monocytes, macrophages, $CD4^+$ T cells, neutrophils, and endothelial cells, the latter being the only cell type in which the expression of p38β is comparable to that of p38α [43]. p38δ is found in the salivary and adrenal glands, testis, pancreas, and small intestine as well as in cells of the immune system, namely $CD4^+$ T cells, macrophages, and neutrophils where it is expressed at levels comparable to p38α. In resting cells p38 is predominantly localized in the cytoplasm. Following cellular activation by stress or inflammatory cytokines, p38 may transit to the nucleus, although the evidence for this is often contradictory and may vary with cell type and state of cellular maturation or activation.

### 2.3 p38 MAPK Signal Transduction

***Classic Signaling Cascade*** The p38 MAPK signaling cascade is strongly activated in vivo in a variety of immune cells in response to a battery of environmental stresses and inflammatory agents (and less so by serum and growth factors that are known to activate ERK MAPK). Human neutrophils alone activate p38 in response to formyl-met-leu-phe (fMLP), granulocyte-macrophage–colony-stimulating factor (GM-CSF), phorbol 12-myristate 13-acetate (PMA), TNF-α, LPS, TGF-β, or ionomycin [44–47]. Stress-associated stimuli commonly trigger the intracellular Rho family of guanosine triphosphate (GTP)-binding proteins, namely Rac1, Cdc42, and Rho [48–51]. The mechanism by which the Rho proteins activate MAP3K has not been entirely elucidated, although it may involve a direct binding interaction that leads to (i) membrane recruitment of MAP3K by upstream activating proteins, (ii) homoligomerization with multiprotein complexes of regulatory components, and (iii) phosphorylation of MAP3K [46, 48–52].

MAP3K are promiscuous, diverse kinases with highly conserved catalytic domains that can interact with a number of regulatory proteins and catalyze the activation of multiple pathways (Fig. 2 and Fig. 3). MAP3K in the p38 cascade include TAK1, ASK1, Tpl-2/Cot, MLK2/3, and MEKK1-4. The abundance and usage of various MAP3K may vary with cell type and reflect particular extracellular stimuli. MAP3K family members activated in the p38 pathway show preference for phosphorylation of the dual specificity MAP2-kinases MKK3 (MEK3), MKK6 (MEK6), and to a lesser extent MKK4 (MEK4), which is usually upstream of JNK but can activate p38 (α and δ isoforms) in response to UV [38]. MKK6 is phosphorylated (Ser207 and Thr 211) in cells exposed to all p38-pathway stimuli, whereas MKK3 appears to be activated (phosphorylation at Ser189 and Thr193) specifically in cells under chemical and physical stress. This may reflect the aforementioned stimuli-specific activation of MAP3K. Consistent with their promiscuous nature, MAP3-kinases have activity toward multiple substrates including those outside the MAPK pathway. For example, MEKK1-3, Tpl-2/Cot, and TAK-1 phosphorylate IKK, an event that releases the transcription factor NFκB from negative regulation [53–55]. MAP2-kinases are also substrates for multiple MAP3Ks. These top two tiers of the cascade are equipped to receive and coordinate responses to multiple divergent inputs and activate multiple, possibly parallel, signaling cascades of both an MAPK-dependent and MAPK-independent nature. While such a system imparts a great deal of biological latitude, elucidation of this part of the pathway is a laborious task, and accurate illustration requires contextual information regarding specific cell types and stimuli.

Finally, MAP3K-activated MAP2K phosphorylate and activate p38 MAPK. MKK6 can activate all four isoforms of p38, whereas MKK3 preferentially catalyze phosphorylation on p38α/β [46, 56, 57].

***Alternative Pathways of Activation*** The activation of p38 in T cells downstream of CD28 or IL12R/IL18R can occur via the conventional MAPK phosphorylation cascade. Alternatively, $CD4^+$ T cells stimulated through the T-cell receptor (TCR) activate p38 independent of the core MAP3K-MAP2K cascade (Fig. 3). In this activation pathway, p38α autophosphorylates (on Thr180

and Tyr182), following initial tyrosine phosphorylation of Tyr323 by Src- or Syk-family kinases Lck and Zap70 [58, 59]. The phosphorylation on Tyr323 is sensitive to Src-tyrosine kinase inhibitors or the presence of DNA-damage-inducible protein 45α (Gadd45α). Gadd45α is an inhibitor of activation-induced T-cell proliferation. Mice deficient in Gadd45α develop T-cell hyperproliferation and autoimmunity and show chronic phosphorylation of p38 [60–62].

It has also been speculated that autophosphorylation of p38 can be mediated by an interaction with scaffold proteins. TAB1 is a cytoplasmic scaffold protein with no catalytic activity that plays a critical role in TLR, TNF-α, and IL-1 signaling pathways. In the conventional signaling pathway, an interaction of TAB1 with TAK1 results in TAK1 autophosphorylation and subsequent activation (phosphorylation) of MKK3/6 and, in turn, p38 (Fig. 3). Through a yeast-two-hybrid screen, TAB1 was identified as a binding partner for p38α. It is speculated that after engagement with TAB1, p38α, like TAK1, would autophosphorylate [63]. A similar phenomenon was observed in mouse embryonic fibroblasts and appeared to involve a disulfide complex with an unknown ~85-kDa protein [64]. It follows that scaffold proteins other than TAB1 may participate in the activation of p38 MAPK. Indeed, the scaffold protein β-arrestin-2 controls the activity of JNK3 [65]. The scaffold proteins JIP1-3, KSR, and MP1 also bind to MAP kinases and should be investigated for the ability to regulate kinase activity and dictate cellular localization [66–68].

***Down Regulation of p38 Activation*** The main players in the dephosphorylation of p38 are (i) dual specificity serine, threonine, and tyrosine phosphatases (DUSP), which dephosphorylate p38α/β, (ii) serine/threonine protein phosphatase type 2C (PP2C) and (iii) protein tyrosine phosphatases, which are responsible for the dephosphorylation of p38γ/δ [69]. Although a mechanism was not elucidated, it was demonstrated that GSK3 can also negatively regulate p38 [70].

DUSPs are present in eukaryotes, including yeast, worms, flies, plants, and mammals. Approximately 30 protein-coding DUSP genes are present in the human genome [71], 11 of which have a MAPK binding domain (MKB) and can dephosphorate MAP kinases. Therefore, these phosphatases are also referred to as MAP kinase phosphatases (MKP) [71–73]. DUSPs have strong amino acid sequence identity (37–75% identity) in their catalytic domains. Three amino acids (Cys, Arg, and Glu) in the highly conserved consensus sequence are essential for enzymatic activity [74]. Mammalian DUSP/MKP have distinct biochemical properties with respect to substrate specificity, subcellular localization, and regulation and are subdivided into three subgroups based on phylogenetics and substrate specificity. MAPK-specific DUSP, which are active toward p38, also have activity for JNK and include DUSP1, 2, 4, 5, 8, 10, and 16 and a low-molecular-mass dual-specificity phosphatase, LMW-DSP2, which lacks the conserved cdc25 homology domain [75–77]. In general, these DUSPs are widely distributed, although DUSP2 is predominantly expressed in hematopoietic tissues, DUSP8 in the brain, heart, and lung, and DUSP10 in the liver and skeletal muscle. The phosphatases have variable subcellular location with some members residing predominantly in the nucleus (p38/JNK-specific DUSP1, 2, 4, 5), others in the cytosolic domain (p38/JNK-specific DUSP16), and others in both the nucleus and cytoplasm (p38/JNK-specific DUSP8, 10). DUSPs are not ubiquitously expressed but are regulated in a cell-type specific manner and/or in response to cellular activation. DUSP1/MKP1 is the archetypal member of the family and an immediate early gene in the innate immune response. DUSP1 can be induced by, amoung others, inflammatory stimuli such as LPS or M-CSF and infection [78]. Mitogenic stimuli causes a rapid induction of high quantities of MKP with messenger ribonucleic acid (mRNA) levels increasing 10- to 100-fold within 15–60 min of exposure to the mitogen. The expression may be controlled posttranscriptionally as mRNA has a short half-life, and ERK-phosphorylation has been shown to increase DUSP1 protein stability [79, 80]. The time course for MKP expression correlates well with the rapid yet transient activation of p38; activity peaks at 15 min and returns to baseline in macrophage cell lines within the first hour following exposure to TLR ligands. Antirheumatic and anti-inflammatory drugs (e.g., glucocorticoids) and anti-inflammatory cytokines (e.g., IL-10) also increase and prolong DUSP1/MKP1 to downregulate p38 signaling and the p38-driven expression of inflammatory mediators [79, 81, 82].

### 2.4 Structure–Function Relationship

In the years following the discovery of p38, extensive in vitro biochemical assays coupled with X-ray crystallography, molecular modeling, and structure–function analyses of p38 and inhibitory CSAID compounds have fueled advances in our understanding about the selective nature of regulatory proteins and CSAID inhibitors for, and differential substrates of, the p38 MAPK family.

Despite a highly conserved activation structure and catalytic domain, the isoforms of p38 differ in amino acid sequence identity, with p38α and p38β sharing 74% amino acid sequence homology and p38γ and p38δ sharing, respectively, 63 and 61% amino acid sequence identity with p38α. Two independent groups

solved the X-ray crystal structure of the inactive, nonphosphorylated form of p38α in 1997–98 [83, 84]. Like other kinases, p38α is comprised of two distinct domains separated by a deep hydrophobic pocket for substrate binding. The N-terminal domain of the molecule is responsible for binding to ATP, whereas the catalytic residues in the C-terminus facilitate the transfer of phosphate from ATP to the substrate. Spanning amino acids 160–185 in the C-terminal kinase subdomain VIII is an activation loop containing a conserved Thr-X-Tyr motif, the phosphoacceptor sequence [46, 85]. This motif is conserved in all MAP kinases where only the X amino acid varies; X is a Glu in ERK, Pro in JNK, and Gly in p38. These amino acids in the context of the full sequence of the activation loop dictate specificity of the various upstream activating MAP2K. Despite a common activation motif in p38α and p38β and 80% homology between MKK3 and MKK6, MKK3 does not activate p38β [56, 57], suggesting that other determinants are involved. MAPK docking sites and other molecular determinants within the N-terminal region of MAP2K also contribute to MAP2K selectivity [86]. A mutant of MKK3 lacking the p38 docking site preferentially phosphorylated tyrosine over threonine residues in the T-G-Y motif on p38α. These data offer evidence that docking sites also influence enzymatic activity [86–89].

MAPK docking sites (also known as D-domains or D-boxes) are present in the upstream activation kinases (MAP2Ks) as well as in MAPK substrates and other MAPK regulator proteins such as phosphatases and scaffold proteins [89]. Competitive binding of activators, substrates, and suppressors to MAPK docking sites may be a mechanism of MAPK regulation, perhaps one that is evolutionarily conserved as docking sites are present in the yeast MAP2K homolog Ste7p. A typical D-domain is comprised of a cluster of positively charged amino acids that are surrounded by hydrophobic residues. D-domains interact with common docking (CD) motifs that consist of acidic and hydrophobic residues and are located outside the catalytic domain in the C-terminus of MAPK [88, 89]. The traditional p38 consensus docking sequence is Arg/Lys-$X_4$-Leu/Ile-X-Leu/Ile, although additional sequences have been identified in several MAPK substrates. For example, a docking site of Leu-X-$(Lys/Arg)_4$ (where X is a hydrophobic residue) was identified in p38 substrates PRAK (p38-regulated/activated protein kinase) and MAPKAPK2. The number of contiguous basic residues following the hydrophobic residues correlates with MAPK specificity. Insertion of the p38 docking site of MAPKAPK2 into the ERK1/2-restricted substrate RSK2 was sufficient to convert RSK2 to a stress-activated kinase in vivo [90].

Molecular modeling predicts that the relative orientation of the MAPK N- and C-terminal domains is altered upon phosphorylation to promote ATP binding, substrate binding, and phosphate transfer. Irrespective of the activation state, CSAIDs bind near the ATP-binding pocket of p38, effectively inhibiting enzymatic activity by exclusion of ATP. SB203580 is the most extensively characterized CSAID and shows specificity for p38α/β MAPK when used at low doses [27, 91]. Located in the hinge of the ATP-binding pocket is a tri-amino-acid sequence Thr106-His107-Leu108 with Thr106 as the key residue controlling selectivity and sensitivity of p38α and p38β to inhibition by CSAID. The CSAID-insensitive p38δ/γ isoforms contain a Met-Pro-Phe sequence in this same position. The introduction of Thr106 or Thr106-His107-Leu108 into p38δ/γ (and JNK) renders these isoforms sensitive to SB203580, and, conversely, substitution of methionine for threonine at position 106 results in a 10-fold reduction in p38α sensitivity to SB203580 [92–94].

Structure–function analyses have identified the molecular determinants that confer enzymatic activity and binding affinity to p38. In vivo, however, the regulation and function of p38 is heavily influenced by multiple factors that are unique to different cell types and their state of activation. Variables include the relative expression and cellular localization of p38 isoforms, phosphatases, kinases, and scaffold proteins. In vivo substrate specificity of activated p38 pathway kinases is in large part determined by cellular accessibility to substrates. The true physiological activity of p38 reflects both the intrinsic biochemical properties of p38 and a given cellular milieu. Scaffold proteins have been ascribed a critical, although perhaps underinvestigated, role in spatial-temporal organization of p38 signaling cascade. Given that p38 MAP kinases have nuclear substrates yet are devoid of a nuclear localization signal, cytoplasmic scaffold proteins and shuttle proteins likely participate in the distribution and regulation of MAP kinases. The D-domain in several p38 substrates (MSK1/2, MAPKAPK2/3, and PRAK) overlaps with their nuclear localization sequence. Thus the engagement of p38 can alter cellular localization of the complex. It has been suggested that both DUSP8 and DUSP16 translocate to the nucleus, then bind, dephosphorylate, and transit p38 to the cytoplasm. These events may also depend on cellular redox states as a reduced form of DUSP1/MKP1 in alveolar macrophages enhanced p38 activity and TNF-α expression [95]. It should be apparent that the p38 pathway is complex and capable of customizing itself to the input stimuli. Therefore, it is advisable to interpret in vivo and in vitro assays addressing mechanisms of MAPK regulation within the specific cellular and environmental conditions under which the experiments were performed.

**TABLE 2 Diversity of p38α/β Substrates**

| Transcription Factors | Protein Kinases | Other |
|---|---|---|
| MEF2A/2C, SAP1/2, ATF2/6, NFAT, CDX3, CHOP/GADD153, PGC-1, p53, USF-1, STAT-1, Elk-1 | MAPKAPK2/K3, MNK1/MNK2, MSK1/MSK2, PRAK | Cdc42, cPLA2, Tau, TAB1-3, NHE-1, keratin8, stathmin, $p47^{phox}$ |

**TABLE 3 Substrates of p38α/β-Activated Kinases**

| p38 MAPK-Activated Kinase | Transcription Factors and DNA Modifying Agents | Binding Proteins, Enzymes, Regulators of Protein Translation |
|---|---|---|
| MAPKAPK2/3 | CREB, CHOP1, ATF1, SRF, ER81, E47 | hsp25, hsp27, TTP, hnRNP, HuR, 14-3-3, 5-lipoxygenase, glycogen synthase, tuberin, eEF2 kinase, PABP1, p16-Arc, TIAR |
| MNK1/2 | ERβ | eIF-4E |
| MSK1/2 | CREB, ATF1, NFκBp65, ER81, STAT3, Histone H3, HMG-14 | Bad, Akt, 4E-BP1 |
| PRAK | | hsp27 |

## 3 EFFECTS MEDIATED BY P38 MAP KINASES

### 3.1 Cellular Effects

***Targets of p38 MAPK*** The substrate specificity of p38 is determined at a molecular level by serine and threonine target residues in the context of proline (e.g., Pro-X-Ser/Thr-Pro) and p38-docking motifs. MAPK-activated protein kinase 2 (MAPKAPK2, MK2), a serine/threonine protein kinase, was the first p38 substrate to be identified [31, 32, 96]. Other substrates include, but are not restricted to, PRAK, MNK, MSK, RSK, cPLA2, ATF2, ATF6, MEF2C, MEF2A, CHOP, $p47^{phox}$, stathmin, Elk1, and SAP1A (Table 2). Most substrates were first identified with the assistance of CSAID compounds and confirmed through the use of p38α heterozygous knockout cells or in p38α–/– embryonic stem cells. The use of p38 inhibitors has favored the identification of p38α/β substrates (over p38δ/γ). However, it does not distinguish between substrates that are unique to the p38α or p38β isoform [97]. Not surprising, p38α and p38β have similar substrate profiles [34], and while some substrates are shared with p38γ and p38δ (such as MBP, ATF2, Elk1) there are some distinctions. For example, p38γ and p38δ do not activate MAPKAPK2/3; however, p38γ can bind to PDZ domains, thereby allowing it to interact with scaffold proteins in plasma membrane-associated cytoskeletal structures such α1-syntrophin, SAP90/PSD95, and SAP97/hDlg [98].

Transcription factors and protein kinases are the major classes of p38 substrates with p38δ and p38γ showing particular preference for transcription factor substrates [99]. The family of MAPK-activated kinases consist of five subfamilies based on sequence homology: RSKs, MSKs, MNKs, MAPKAPK2/3 (MK2/3), and MAPKAPK5 (MK5). p38-induced activation of MAPKAPK results in the downstream engagement of both cytosolic and nuclear substrates, which are unique to MAPKAP-kinases, many of which are involved in regulating gene transcription and protein translation (Table 3). Some MAPKAP-kinases have nuclear localization signals and are exclusive residents of the nucleus, thereby enabling activation of transcription factors such as the basic-leucine zipper (bZIP) transcription factor CREB (cyclic adenosine monophocphate [cAMP] response element [CRE] binding protein). As the name implies, CREB binds to certain sequences called cyclic adenosine monophocphate (cAMP) response elements (CRE) in DNA and transactivates the expression of genes such as TNF-α, IL-1, and IL-6 [100, 101]. The p38-induced activation of protein kinases bestows a secondary set of substrates to p38 that participate in the regulation of inflammatory mediators [102, 103].

***p38 MAPK Control over the Expression of Inflammatory Mediators*** The expression of inflammatory mediators can be complex and requires the contribution of multiple factors that influence gene transcription and translation. The most prominent transcription factors and coactivators that are required for the transcription of inflammatory genes include NFκB, AP1, p38, and C/EBP (CCAAT-enhancer binding protein) [1]. The expression of inflammatory mediators, in particular, pro-inflammatory cytokines, is also heavily dependent on factors that promote mRNA stabilization and protein translation. AU-rich elements (AREs) are common elements of the 3′ untranslated region (3′UTR) of inflammatory protein mRNA [1]. When complexed with AU-binding proteins, the transcripts are destabilized and degraded. The shortest strongly destabilizing

sequence thus far identified is the 34-nucleotide TNF-α ARE that contains six AUUUA motifs [104]. The prototypic zinc finger protein ZFP36 (tristetraprolin/TTP) inhibits TNF-α secretion from murine macrophages by binding the ARE and destabilizing TNF-α mRNA [105–107]. Inhibition of any one regulatory factor often results in a partial, not complete, abrogation of inflammatory protein expression.

Inflammatory genes regulated downstream of p38α/β activation were discovered by the use of the CSAID as well as inactive and constitutively active mutants of upstream kinases and downstream substrates of p38. There is significant diversity in the genes that are activated by p38 MAPK, which likely reflects the diversity of substrates that can be activated by p38 and p38-activated kinases. There is evidence that p38 controls the expression of cytokines (TNF-α, IL-1, IL-6, RANKL), chemokines (IL-8, IP-10, MCP-1, MIP-1α/β), extracellular matrix (ECM)-modifying enzymes (MMP1, 3), inflammatory enzymes (COX-2, NO synthase), cell adhesion molecules (ICAM-1), and growth factors (GM-CSF) [99].

Inhibition of p38 can have differential effects on mRNA and protein levels, a phenomenon commonly described for the expression of TNF-α [104, 108]. While not all ARE-containing mRNAs are regulated by p38, evidence exists for p38-dependent stabilization of TNF-α, IL-1β, GROα, IL-6, GM-CSF, COX-2, c-Fos, and IL-8 mRNA [1, 99, 108]. p38-induced activation of MAPKAPK2 and MNK1/2 results in, respectively, the activation of tristetraprolin (TTP) and eukaryotic initiation factor 4E (eIF-4E). TTP is an mRNA destabilizing element and eIF-4E a component of the eIF-4F protein complex that unwinds mRNA secondary structure and promotes the initiation of protein translation. Consistent with these findings, MAPKAPK2-deficient mice have impaired protein synthesis of TNF-α but normal levels of TNF-α mRNA. Accordingly, TTP null mice spontaneously express TNF-α as do mice deficient in the TNF-α 3′UTR AU-element. TNF-α production in TTP and TNF-α ARE knockout, but not wild type, mice were insensitive to p38 MAP kinase inhibitors despite normal activation of the upstream components of the p38 MAPK pathway [109, 110]. While the details concerning the connectivity between AU-binding proteins such as AUF1, HuR, TTP and the p38 pathway are not well established, stimuli-induced activation of p38 and subsequently MAPKAPK2 may result in, for example, the phosphorylation and release of TTP from TNF-α mRNA and subsequent expression of TNF-α protein [106, 107, 111, 112]. Therefore the regulation of inflammatory protein expression by p38 includes both transcriptional and posttranscriptional mechanisms. In response to stimuli such as IL-1, TNF-α, TLR, and stress (UV), p38 MAPK can

1. *Directly activate transcription factors*, for example, Elk-1 and SAP-1 [1, 46, 99] that control the expression of genes for inflammatory agents.
2. *Promote gene transcription via indirect activation of transcription factors and induction of transactivating factors and modifications to DNA that promote transcription*. p38 via MSK1/2 can activate CREB, NFκB subunit p65, phosphorylate histone H3 (to recruit NFκB) and TATA box binding protein TFIIDa, and activate high mobility group protein 14 (HMG-14) to remodel chromatin and promote transcription [113–115].
3. *Promote mRNA stability and protein translation* to facilitate rapid control over the expression of inflammatory agents. This can be achieved indirectly through MAPKAPK2-mediated phosphorylation of AU-binding proteins and stabilization of ARE-containing mRNA and via MNK-mediated activation of eIF-4E [109, 116–119].

The activation of p38 through different pathways may manifest in the activation of distinct substrates and diverse cellular functions. Indeed, TAB1-dependent activation of p38 stimulated a set of substrates that were distinct from those downstream of p38 when activated by MAP2K [120] and has been linked specifically to the maturation of monocyte-derived dendritic cells, induction and maintenance of peripheral T-cell anergy and intracellular infection, parasite-induced IL-12 production, and myocardial ischemia [62, 120–123]. In addition, TAB1 may become a substrate of p38 following activation in complexes of TAB1-TAK1-TAB2/3. Phosphorylated TAB1 inhibits TAK1 that would mediate a negative feedback loop on the activation of p38, TAK1, and IKK/NFκB in response to inflammatory stimuli. Furthermore, sequestration of p38 to one pathway may inhibit participation in other signaling pathways, responsiveness to new divergent inputs, and altered availability to substrates and regulators [124].

### 3.2 Biological Effects

A single genetic knockout of murine p38β, p38γ, and p38δ as well as a double knockout of p38γ/δ had no observable impact on birth frequency, size, or health of these mice. On the other hand, p38α is without question an essential kinase in embryogenesis [22, 125–128]. In the absence of viable p38α-deficient mice and no discernable phenotype in mice deficient in the other p38 isoforms, p38-inhibitor compounds have been used extensively to evaluate the role(s) for p38 in vivo. New generations of p38 inhibitors have improved specificity, yet CSAID toxicity and off-target effects within an already complex, functionally redundant and cellularly diverse p38 signaling pathway, can shed doubt on the

**Figure 4** Inflammatory roles of p38 MAPK. Dysregulation of any number of the cellular and physiological functions depicted in the core of the illustration can drive the development of adverse inflammatory disorders and diseases, examples of which are given on the periphery of the diagram.

authenticity of any physiological role(s) of p38 that are revealed using the chemical inhibitors. While the inhibitors are convenient to use for in vitro and in vivo experiments, biological roles should be confirmed using another system, for example, heterozygous knockout mice (p38α+/−), tissue-specific homozygous p38α depletion (e.g., in cardiac muscle), transgenic mice expressing a dominant negative form of p38α (dnp38a, T180A/Y182F) and/or in mice with genetic deletion of p38α substrates and activators. An ever increasing amount of in vitro and in vivo evidence using different model systems substantiates a role for p38α in inflammation, inflammation-mediated disease, and inflammatory pain including, but not limited to, rheumatoid arthritis (RA), inflammatory bowel disease (IBD), acute respiratory distress, ischemic heart disease, and sensitivity to pain (Fig. 4 and Table 4) [14, 129–140].

***Inflammatory Disease*** The chronic inflammatory disease RA is caused by an inflammatory mass of activated leukocytes in the synovium, 70% of which are $CD4^+$ T cells (50%) and macrophages (20%), with the remaining 30% of cells comprised of dendritic cells and B lymphocytes. The disease is driven by the overproduction of (p38-regulated) genes, including IL-1, TNF-α, RANKL, IL-6, GM-CSF, COX-2, collagenases, and MMPs that enhance inflammatory pain and promote bone and cartilage erosion. Badger et al. demonstrated that p38α/β and p38α-specific CSAID blocked LPS-induced TNF-α production in mice and reduced joint edema in the collagen-induced arthritic model. The p38α/β CSAID SB203580 was also effective at blocking IL-1-induced nitric oxide in bovine articular cartilage explants and chondrocytes and reduced serum TNF-α and protected against LPS/D-gal-induced endotoxic shock [141]. Subsequent experiments demonstrated that inhibitors with greater selectivity for the p38α isoform (SB242235, R130823 and SD282, indole-5-carboxamide) blocked paw swelling in the collagen-induced arthritic model and in the adjuvant arthritic rat model [133, 142, 143]. Since p38β-deficient mice show no defect in cytokine production [22, 144, 145], it has generally been accepted that p38α is the dominant isoform to mediate inflammation, and effects of CSAID are due to inhibition of the p38α rather than p38β isoform. O'Keefe et al. recently used a combination of specific genetic mutations and pharmacological techniques to conclusively demonstrate that only p38α is involved in acute

**TABLE 4 Sampling of in vitro and in vivo Evidence for p38α/β in the Inflammatory Response and Inflammatory Disease**

| Role | Assay System/ Model | | Observation | Reference |
|---|---|---|---|---|
| Inflammation; chemokine production | p38α/β inhibitor SB202190, SB203580, dominant negative MKK6 & constitutively active MKK6 | in vitro | Inhibitors and dominant negative MKK6 blocked TNF-α-induced MCP1 in HUVEC (and human mesangial cells)<br>Constitutively active MKK6 enhanced TNF-α-induced MCP1 in HUVEC | 259, 260 |

| Inflammation; Arthritis | Inflammed tissue from patients with RA | ex vivo | p38α and p38γ found are most prevalent isoforms | 269 |
| | p38α/β inhibitors | in vivo | Reduced paw inflammation in the adjuvant arthritic rat model and joint edema in the collagen-induced arthritis model | 141, 142 |
| | p38α inhibitor R130823 | in vivo | Efficacy in mouse and rat models of arthritis | 143 |
| | p38α inhibitor | in vivo | New synthesis of 2-amino-benzimidazole inhibitor with efficacy in rat collagen-induced arthritis model | 270 |
| | p38α inhibitor TAK-715 | in vivo | Efficacy in adjuvant-induced rat arthritis | 196 |
| | p38α inhibitor VGX1027 | in vivo | Reduced paw swelling in collagen- and polysaccharide-induced arthritis model | 194 |
| | p38α inhibitor SD-282 | in vivo | Reduction in LPS-induced inflammatory cytokine production, osteoclast formation, and alveolar bone loss | 133 |
| | $p38\alpha^{ki/ki}$ and $p38\beta^{ki/ki}$ T106M knock in mice are enzymatically active and insensitive to CSAID | in vivo | CSAID MRK48 reduced LPS-induced TNF-α and collagen antibody-induced arthritis in $p38\beta^{ki/ki}$ but not $p38\alpha^{ki/ki}$ mice p38α specifically involved in inflammation | 146 |
| | $MKK3^{-/-}$ | in vivo | Markedly decreased the severity of arthritis (production of inflammatory agents and cellular infiltration) in passive K/BxN model of arthritis or in response to LPS challenge | 233 |
| Inflammation; Asthma | p38α/β inhibitor SB203580 | in vivo | Attentuated BAL TNF-α production in rat model of allergen-induced asthma | 159 |
| | Aerosolized p38α antisense oligo (p38α-ASO) | in vivo | Inhibited ovalbumin-induced inflammatory cells, IL-4, IL-5, IL-13 in BAL, pulmonary eosinophilia, mucus hypersecretion, and airway hyperresponsiveness | 160 |
| Inflammation; COPD | Lung tissue samples from smokers with COPD | ex vivo | Increased phosphorylated p38 in alveolar macrophages | 135 |
| | p38α inhibitor SB2439063 | in vivo | Inhibited inflammatory mediators and bleomycin-induced right-ventricular hypertrophy in models of COPD and lung fibrosis | 267 |
| | p38α inhibitor SD-282 | in vivo | Inhibited infiltration of macrophages and neutrophils and inflammatory mediators (COX-2, IL6) in tobacco-smoke-induced pulmonary inflammation model | 161 |
| Inflammation; Acute lung | p38α and p38α/β inhibitors SD282 and SB239063 | ex vivo | Decreased LPS-induced TNF-α and GM-CSF in macrophages isolated from lung tissue of smokers, ex-smokers, emphysema patients | 162 |
| | p38α/β inhibitor SB203580 | in vivo | Reduced IL-1β and neutrophilia in rat aerosolized LPS challenge | 163 |
| | p38α/β inhibitor M39 | in vivo | Systemic inhibition decreased TNF-α and neutrophil accumulation in airspaces following intratracheal administration of LPS | 136 |
| Inflammation; atherosclerosis | p38α/β inhibitor SB203580 | in vitro | Attentuated thrombin-induced vascular smooth muscle cell migration and expression of VEGF | 271 |

**TABLE 4** ***Continued***

| Role | Assay System/ Model | | Observation | Reference |
|---|---|---|---|---|
| Inflammation; myocardial apoptosis and injury | Adenoviral expression of p38 in cardiomyocytes | in vitro | Activation of p38α caused apoptosis, whereas activation of p38β mediated protective hypertrophic response | 272 |
| | p38α inhibitor SD282 | in vivo | Improved cardiac function (stroke volume, cardiac output), reduced macrophage infiltration of inflammatory cells and abolished cardiomyocyte apoptosis in a rat model of myocardial injury | 137 |
| Inflammation; apoptosis | MAPKAPK2$^{-/-}$ | in vivo | Decreased IL-1β and focal ischemic brain injury | 164 |
| Inflammation; pain | p38α inhibitor R130823 | in vivo | Blocked hyperalgesia in rat adjuvant-induced arthritis | 143 |
| | p38α/β inhibitor SB203580 | in vivo | Reduced spinal nerve ligation induced mechanical allodynia (neuropathic pain) | 185, 186 |
| | p38α/β inhibitor SB203580 and p38α inhibitor SD-282 (Scios) | in vivo | Reduced thermal hyperalgesia and spinal activation | 187, 188 |
| Immunity; lymphocyte function | p38α inhibitor SCIO469 | in vitro | Suppressed IL-6 and VEGF and multiple myeloma proliferation | 138 |
| | Murine thymocytes | in vivo | Expresssion of p38 is required for early stages of T-cell development and induces apoptosis in CD8$^{+}$ but not CD4$^{+}$ T cells | 60, 273 |
| | p38α/β inhibitor SB203580 and dominant negative p38α (dnp38aT180A/Y 182F expressed under the lck promoter in transgenic B10Br) | in vivo | Chemical inhibitor blocked IFNγ production by Th1 cells but not IL4 by Th2 cells and dominant negative p38 impaired Th1 responses | 59, 273 |
| Immunity; bacterial/viral clearance | p38α/β inhibitor SB203580 | in vitro | Inhibited activation of neutrophil NADPH oxidase | 274 |
| | MAPKAPK2$^{-/-}$ | in vivo | Normal levels of IL-lβ, IL-6, NO, and ROS, decreased TNF-α and IFNγ production, enhanced bacterial load, and increased susceptibility to *Listeria* monocytogenes | 275 |
| | Murine models of infection | in vivo | Increased cytokine production and decreased bacterial clearance in mouse models of pneumococcal pneumonia and tuberculosis | 276 |
| | Various | in vitro in vivo | Antiviral and antiproliferative effects on hematopoiesis and tumorigenesis mediated by type I interferons | 277 |
| Inflammation and immunity | MKK3/MKK6 single and double KO | | MKK3/MKK6 double KO are not viable while single KO are viable; therefore likely have redundant roles | 278–280 |
| | MSK1 and MSK2 single and double KO | | No phenotype in single or double knockout | 103, 113 |
| | MK5$^{-/-}$ | | No phenotype and MK2/MK5 double knockout has the same phenotype as MK2 single knockout | 281 |

and chronic inflammation [146]. Based on the observation that Thr106Met substitution does not alter p38α/β kinase activity but does confer resistance to inhibition by CSAID [84, 93, 94], O'Keefe et al. constructed both p38α Thr106Met and p38β Thr106Met knock-in mice. p38α Thr106Met mice, but not p38β Thr106Met mice, were resistant to pharmacological inhibition (by CSAID MRK48) of LPS-induced TNF-α and collagen-induced arthritis. This concurs with a normal inflammatory response observed in p38β knockout mice, and results by Beardmore et al. of similar TNF-α production in wild type and p38β knockout mice in an LPS/D-gal challenge model and sensitivity of p38β knockout mice (in terms of TNF-α production) to SB203580 [144].

The inflammatory phenotypes observed in vivo using chemical inhibition have been substantiated using MAPKAP2, TNF-α, and DUSP1/MKP1 knockout mice. TNF-α ARE-deficient mice consitutitively produce high levels of TNF-α and develop pathologies similar to chronic inflammatory arthritis and Crohn's inflammatory bowel disease [110, 111, 147]. In human TNF-α transgenic mice, p38 activity contributed to the development of arthritis [148]. Mice deficient in MAPKAP2 are protected from endotoxic shock and are resistant to collagen-induced arthritis [103, 149]. As seen in vitro using pharmacological inhibition of DUSP1/MKP1 or overexpression of an MKP1 catalytic mutant, p38 (and JNK) activation was prolonged in vivo in MKP1–/– mice. TLR agonists also induced greater pro-inflammatory cytokines (TNF-α, IL-6, IL-10) and chemokines (MIP1α, MIP1β, MIP2) in MKP–/– animals [95]. The MKP1 knockout mice develop more severe collagen-induced arthritis, impaired kidney function, multiorgan dysfunction, and enhanced mortality [95, 150–153].

In chronic obstructive pulmonary disease (COPD) and asthma (airway inflammation), inflammatory cytokines and chemokines such as TNF-α, IFNγ, IL-4, IL-5, IL-8, RANTES, and eotaxin are important components of the disease [154, 155]. Pulmonary hypertension is believed to lead to chronic hypoxia [155], and hypoxic stimulation of pulmonary artery cells is also mediated by SAPKs [156]. An inhibitor of p38 blocked LPS- and TNF-α-induced CD54/ICAM1 expression on pulmonary microvascular endothelial cells [157], and bronchial epithelial cells exposed to a hyperosmolar medium produced IL-8 by a MAPK-dependent mechanism [158]. In a rat model of allergen-induced asthma, the p38α/β CSAID SB203580 blocked the production of TNF-α [159]. Along similar lines, aerosolized p38α antisense oligo was effective at inhibiting inflammatory mediators and airway hyperresponsiveness [160]. Various CSAID have proven effective at blocking cellular infiltration in chronic and acute lung models (Table 4) [136, 160–163], and an increased expression of phosphorylated p38 was detected in alveolar macrophages isolated from the lung tissue of smokers with COPD [135].

Heart, stroke, and atherosclerotic vascular disease are the leading cause of death in the United States each year. p38 plays a significant role in the control of apoptotic cell death and ischemia in cardiomyoctes, which appears to be isoform specific [164, 165]. The p38α isoform-specific inhibitor SD282 enhanced heart function and abolished apoptosis in a rat model of myocardial injury [137]. The role of p38 as a therapeutic target in heart disease was described extensively in a recent review by Clark et al. [166].

Multiple myeloma is a cancer affecting plasma B cells that is driven by cytokines and growth factors such as IL-6 and vascular endothelial growth factor (VEGF). Cross-linking CD40 on B cells stimulates p38 and MAPKAPK2 and results in NFκB activation, cell proliferation, and the induction of the cell adhesion molecule CD54/ICAM1. All inducible events were inhibited by CSAID SB203580 [167]. Another inhibitor of p38 (VX-745) blocked IL-6 and VEGF production by bone marrow stromal cells and subsequently inhibited paracrine-induced multiple myeloma cell growth [168]. An inhibitor of p38 in clinical trials for multiple myeloma (SCIO-469) increased susceptibility of the myelomas to killing by proteasome inhibitors [138, 169].

The cytokine RANKL and chemokine MIP1α are expressed in a p38-dependent manner by myelomas [170]. Also in a p38-dependent manner, RANKL drives the formation of osteolytic bone lesions that are associated with this type of cancer. An analogous process is at work in rheumatoid arthritis. Here, RANKL is produced by T cells and RANKL-induced osteoclast differentiation mediated by p38 causes bone erosion associated with RA [170–173].

These data indicate that p38α contributes to the inflammatory disease in vivo, and inhibition of p38 was sufficient to reduce the severity of disease.

***Pain*** Inflammatory mediators, via a p38-dependent mechanism, stimulate the production of inflammatory mediators and neuroactive substances. Neuroactive peptides and inflammatory cytokines are overexpressed in the spinal cord in peripheral inflammatory and neuropathic experimental models of pain. The synthesis of inflammatory mediators and neuroactive substances that act on nociceptive neurons is dependent on p38 MAPK. IL-1β-stimulated p38 in turn induced iNOS and the production of NO. The production of NO caused sensitization of spinal cord nociceptors and thermal hyperalgesia (heightened perceptions of pain) and allodynia (perceived pain when there should be none)

[174–176]. Inhibitors of IL-1β, p38, or iNOS block NO production and sensitization [177, 178]. Primary sensory neurons and p38 are also reactive to inflammation-induced neuronal growth factor (NGF). Here, p38 drives the expression of TRPV1/VR-1, a transient receptor potential/heat gated ion channel causing enhanced inflammatory heat hyperanalgesia and heightened perception of pain [179]. The negative controls on p38 in this system are not well known, and, unless the positive feedback loop is broken, chronically inflamed nociceptors continue to transmit a barrage of signals to the nervous system, causing chronic sensitization and heightened, continuous feelings of pain.

Flavonoids are present in plants and are believed to possess natural antioxidant and anti-inflammatory properties. It is known that flavinoids can inhibit protein kinases and reduce ERK and JNK phosphorylation in carcinoma cells. The flavonoid myricitrin has antinociceptive effects in experimental models of acute and chronic pain. This was shown previously to involve decreased PKC and NFκB activation, NO production, altered $Ca^{2+}$ and $K^{+}$, and activation of G protein pathways [180]. Meotti et al. further demonstrate that myricitrin inhibits p38, but not ERK1/2 or JNK1/2, phosphorylation in response to cytokine stimulation and prevented TNF-α- and IL-1β-induced biting behavior in mice [181].

Opioid peptides [e.g., Met-enkephalin (ENK) and B-endorphin (END)] bind to cognate receptors on peripheral sensory nerves and locally inhibit pain. Polymorphonuclear (PMN) cells are the major source of opioid-mediated pain control during the early phase of inflammation. Depletion of PMN abolishes antinociception induced by inflammatory chemokines (CXCL2/3). The effect can be reversed by a local injection of allogenic PMN [182, 183]. p38 MAPK mediate the chemkine-induced release of opioid peptide and subsequent pain control. Chemokine-induced release of opioid peptides from human PMN intracellular vesicles in vivo can be blocked by antipeptide antibodies as well as by inhibitors of p38 but not ERK1/2 [184, 185].

It appears then that p38 can have dual effects in the regulation of pain; contributing to pain through the stimulation of neuroactive peptides and inflammatory mediators and reducing pain by inducing neutrophil release of opioid peptides. In vivo, inhibition of p38 blocked hyperalgesia and mechanical allodynia in various rodent models of pain [143, 184–188], and, clinically, inhibition of p38 showed enhanced efficacy in pain control compared to ibuprofen, a hallmark discovery for the use of p38 as an analgesic [189]. Improved mechanistic information for the induction and maintenance of neural plasticity is required to further the development of effective drug regimes to control acute and chronic pain [2, 190].

## 4 P38 MAPK AS A THERAPEUTIC TARGET

Nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin and ibuprofen have analgesic, antipyretic, and anti-inflammatory effects and are currently the most efficacious treatment to reduce inflammation, fever, and pain. Immunomodulatory agents, often referred to as biologic response modifiers (BRM) such as the TNF-α blocker drugs Enbrel (etanercept; soluble TNF-α receptor), Remicade (infliximab), and Humira (adalimumab; anti-TNF-α antibodies) as well as Kineret (anakinra), an IL-1 antagonist, have also seen success in the treatment of inflammatory diseases. The investigation into p38 as a potential therapeutic target began shortly following the fortuitous discovery of p38 coincident with the discovery of a crucial p38 substrate (MAPKAPK2) and a potent inhbitor that blocked inflammatory cytokine production. Several recent reviews have discussed the potential of p38 as a therapeutic agent for the treatment of a number of diseases [129, 130, 133, 134, 139, 140, 154, 176, 189, 191–198].

It is anticipated that compounds that inhibit p38 will confer a significant clinical benefit over current anti-inflammatory therapies at the very least for diseases in which anti-TNF-α therapy has already proven effective (e.g., RA, psoriasis, Crohn's disease). Unlike current therapies that generate a clinical anti-inflammatory effect by inhibition of a single inflammatory mediator (TNF-α, IL-1β, or COX-2), the suppression of p38 would simultaneously influence the production of multiple inflammatory agents. This feature should have superior efficicacy, which has already been observed clinically when anti-TNF-α and anti-IL-1β therapies were used in combination [199]. In addition to blocking the cellular expression of inflammatory mediators, anti-p38 compounds have the added benefit of blocking cellular responses to those mediators (including TNF-α, IL-1β, and RANKL). Inhibition of a multifunctional protein such as p38 may confer a significant advantage over current biologic therapies such as the ability to achieve positive results clinically with inhibitors that possess only moderate inhibitory potency towards p38. From a therapeutic perspective, it is also important to recognize that p38 participates in processes within both the immune and nervous system, and p38-regulated inflammatory agents mediate cross-talk between the two systems. Hence anti-p38 inhibitors are primed to have dual anti-inflammatory and anti-analgesic effects and could be administered for use in multiple clinical applications for the treatment of acute and chronic inflammatory diseases and pain. The oral bioavailability of p38 inhibitors significantly reduces the economic load associated with the therapy and imparts a convenient drug administration regime.

### 4.1 Previous Successes and Failures

The prototypic CSAID SB203580 has served as a template for the generation of other CSAID pryidinyl-imidazole inhibitors and new classes of small molecule inhibitors of p38. Much of this work has been the result of detailed molecular modeling and crystal/co-crystal structures of p38 and pryidinyl-imidazole group inhibitors [83, 84]. Pyridinyl-pyrazole scaffold inhibitors emerged as the second generation of p38 inhibitors. They were designed to have increased activity and selectivity with reduced toxic side effects and were generated by substitutions to the imidazole ring of pryidinyl-imidazole compounds. VX-745 (Vertex Pharmaceuticals) is an inhibitor in this class that achieved enhanced selectivity for p38 over JNK and ERK via the altered orientation of a small glycine amino acid that is located at position 110 in p38 but not in ERK or JNK. Both pyridinyl-imidazole and pyridinyl-pyrazole inhibitors lie in the ATP-binding pocket of p38 and rely on competitive inhibition of ATP to block p38 enzymatic activity [200, 201]. In contrast, the third class of p38 inhibitors to materialize, diaryl ureas, engage sites away from the ATP-binding pocket. Binding of these inhibitors to p38 disrupts the activation loop and blocks phosphorylation of p38, thereby locking it in an inactive conformation [202]. Several other classes of p38 inhibitors have been developed, including substituted benzamides, diaryl ketones (e.g., RO201195), and indole amides (e.g., SCIO469 and 323). The chemical structure and synthesis of p38 inhibitors has been recently reviewed by several groups [195, 198, 203–209].

By 2005, more than 20 potent p38 inhibitors, including BIRB-796, SCIO469, and VX702, had been designed with enhanced selectivity over the original pryidinyl-imidazole inhibitors. Preclinical studies demonstrated that each of these inhibitors reduced, in vitro and in vivo, inflammatory cytokine production and were effective in vivo in various models of animal disease (examples given in Table 4). With the significant promise bestowed on these compounds by the in vitro and in vivo studies, many inhibitors entered clinical trials to treat a range of inflammatory diseases. Preliminary studies demonstrated that AMG 548 (produced by Amgen) blocked LPS-induced TNF-α and IL-1β release and TNF-α-induced IL-8 release in whole blood, had 85% inhibition of TNF-α and IL-1β ex vivo, and was effective against collagen- and adjuvant-induced arthritis in rats. AMG 548 was suspended from future investigation as a human therapeutic due to random elevations in liver enzymes. Similarly, clinical trials with BIRB796 (Boehringer Ingelheim) were discontinued due to a suspected negative impact on liver enzyme production and, disappointingly, no observed efficacy against Crohn's disease [210] despite effectiveness in human endotoxin challenge. Unfortunately, many other

[a]Inhibitor of MEK; all other compounds are inhibitors of p38α or p38α/β.

p38 inhibitors have met the same fate and have failed to advance through human clinical trials (Table 5) [139, 140, 198, 211–213].

Deleterious unforeseen effects of p38 inhibitors that come to light in clinical trials are likely the result of insufficient biological information rather than failures associated with the structure–function relationship between p38 and the inhibitor. Such academic drawbacks may include a lack of sufficient knowledge regarding detailed MAPK pathways and cross-talk in the MAPK family under basal and disease conditions and/or incomplete understanding of the role(s) of MAPK in biological processes. Inhibitors were most commonly withdrawn from the clinic due to what appeared to be off-target, toxic effects. Pyridinyl imidazoles were discovered to interact with hepatic cytochrome p450 liver enzymes involved in drug metabolism [214], which is the most likely explanation for the observed liver toxicity with many of the original p38 inhibitors. This finding is also important as it demonstrates that the compound (pyridinyl imidazole) itself, not the target (p38), was the cause of toxicity, thereby preserving the reputation of p38 as a safe and viable drug target. The focus now is to build on the progress and failures of previous p38 inhibitors as therapeutic agents, honing selectivity to decrease off-target effects and toxicity. The most effective p38 inhibitors may share certain general properties (summarized in Table 6) and may be those that reduce but do not abrogate the production of all inflammatory mediators. In this manner, they can selectively modulate aspects of inflammation while maintaining normal physiological functions and a relatively normal balance between positive and negative regulatory pathways [215].

**TABLE 6 Properties of Safe and Efficacious Therapeutic Agents**

***Potent***
- Interact with inactive and active modules of the target protein
- Interact with a region on the target protein that has a selective advantage over in vivo competitors (e.g., targeting regions of p38 separate from those utilized by ATP)
- The therapeutic target is multifunctional, thereby inhibition (or activation) produces the desired physiological outcome through multiple avenues (e.g., p38 can inhibit cytokine production and cytokine-mediated signaling)

***Selective***
- Avoid targeting conserved domains or ubiquitously expressed molecules
- All biological roles of the target protein and any relevant splice variants have been deciphered
- Target molecules have a well-defined role in the disease of interest

***Safe***
- Aberrant function of the target protein does not provoke undesired effects in other systems (e.g., anti-inflammatory agents can compromise immunity)
- All biological roles of the target protein and any relevant splice variants have been deciphered
- Targets do not impair essential cellular processes (e.g., gene transcription)

### 4.2 Moving Forward

***New p38 Inhibitory Compounds*** Early counter-screens of CSAID cross-reactivity for other kinases were rather modest and suggested that these compounds had specific activity toward p38α/β. It has become apparent, however, that this is not the case. With a high degree of structural conservation in the adenosine binding pocket and functional redundancy within the approximately 520 kinases in the human genome [9], it is not wholly unsurprising that, while showing preference for some kinases over others, the CSAIDs are not monogamous inhibitors. The well-characterized and widely used SB2300580 CSAID has measurable enzymatic activity and binding reactivity with nonenzymatically active cellular proteins and cellular kinases, including enzymes from distantly related families, for example, GAK, CKII, JNK, Raf, Lck, GSK3β, PRKα, and RICK, with reactivity toward RICK equivalent to that for p38α/β [198, 216–218]. Some of these kinases are critical in the inflammatory and immune response and may have positively contributed to the anti-inflammatory action observed in vitro and in vivo with this inhibitor. On the other hand, it is also possible that inhibition of these kinases may cause immune suppression or negative effects on other organ systems in a clinical setting [219, 220]. Without a doubt it is an imposing task to achieve substrate specificity with kinase inhibitors that target the ATP-binding pocket. Nevertheless, some kinase inhibitors have been used successfully to treat cancer. Licensed drugs include ABL kinase (Gleevec) from Novartis and EGFR kinase (Iressa) from AstraZeneca [221], and synthetic blockers of MAP kinases are showing promise in the treatment of myelomas [138, 222, 223]. Current p38 inhibitors that bind the ATP-binding pocket can do so on both the inactive, nonphophorylated and active, phosphorylated forms of p38. In contrast, ATP can only engage the active form of p38, which gives the inhibitor a competitive advantage over ATP and eliminates the need for extremely high levels of potency in vivo in order to contend with the presence of millimolar levels of cellular ATP [224, 225]. Nevertheless, it may be advisable to avoid the highly conserved ATP-binding site and target an allosteric site in p38 MAP kinases to reduce

possible off-target effects on proteins with identical or similar functional domains. This should minimize laborious screening of the inhbitor for cross-reactivity with other kinases [140]. BIRB796 has been the prototype for inhibitors that do not engage the ATP-binding pocket and that possess slowed dissociation rates ($t_{1/2}$ of 24 h) compared to the ATP-binding pocket directed inhibitors ($t_{1/2}$ of 1 min). Moss et al. have recently reported new methods using synchronized crystallographic structure information, chemical properties, and molecular modeling to design new classes of inhibitors with BIRB-like features. The resulting compounds diminish TNF-α release from THP1 cells, whole human blood, and LPS-treated mice [208]. Natarajan et al. define a new subclass of pyridinyl-pyrazole p38α inhibitors, the 7-amino-naphthyridones. Selected molecules from this class demonstrated potent inhibition of p38 and blocked TNF-α release in human whole blood, in a LPS challenge model when given orally 27.5 h prior to LPS and in rats where inhibition of TNF-α was similar or better than that achieved with dexamethasone. In addition, the inhibitors were effective in models of disease, showing efficacy in a rat antigen-induced arthritis model [209]. A host of other computer- and structural biology-aided methods have been used to design inhibitors of p38 such as 3D- and 4D-QSAR modeling [226, 227]. There are a number of excellent publications providing detailed discussions of structure and activity relationships (SAR) and molecular modeling of p38 inhibitors [198, 203, 228–231]. This sort of combined approach using detailed structure–function analyses, X-ray crystallography, and site-directed mutagenesis studies will continue to provide a strong molecular basis to understand the selectivity of p38 inhibitors and to design new inhibitors. Lee and Dominguez suggest that every kinase-specific difference in structure should be exploited in order to discover inhibitors with true selectivity and specificity [198].

***Alternative Targets*** These same techniques can be applied to the design of inhibitors that target p38-interacting proteins in order to suppress p38 [232]. In this manner the inherent difficulties in explicitly targeting molecules with highly conserved regions of activity and functional redundancy can be avoided, and a new pool of proteins on the periphery of the central MAP3K-MAP2K-MAPK pathway can be considered for their potential as safe and efficacious targets to downregulate p38. Potential molecules of interest include MKK3, MKK6, MAPKAPK2, and PRAK. MKK3 deficiency markedly decreased the severity of synovial inflammation in spontaneous arthritis in the KRN transgenic mouse (K/BxN model of arthritis) [233]. MAPKAPK2 has been deemed the most important substrate to execute the inflammatory properties of p38. The knockout mice have an anti-inflammatory phenotype and, most conveniently, have decreased levels of p38α [103]. Efforts are underway to find natural MK2 inhibitors [234]. Small-molecule inhibitors that induce a conformational change in p38 also provide a structural basis for the rational design of inhibitors that induce an inactivating conformation, for example, one that excludes ATP binding or alters substrate interactions. Mutations in the hydrophobic core can cause a conformational change that allows autophosphorylation of p38 [235]. A similar conformational change is induced by TAB1 and may explain the observed autophosphorylation of p38. Small-molecule inhibitors that disrupt p38-TAB1 interactions (or p38 autophosphorylation) may yield specific benefits in myocardial ischemia and TLR-induced inflammatory responses [121]. Studies using MKP/DUSP knockout mice define a critical role of this family of phosphatases in controlling p38 activity. Very small changes in MKP expression is sufficient to drastically downregulate p38 activity and MKP1–/– mice are impaired in their ability to control inflammation. While MAPK phosphatases should not be excluded as potential targets to modulate p38 activity, consideration needs to be given to the impact of these phosphatases in particular on JNK MAPK and other non-MAPK substrates. As a general rule, any serious investigation of new targets to regulate p38 function should be restricted to molecules that have activity exclusively within the p38 pathway and a well-defined role in inflammatory disease.

***Natural Products*** Insight into novel targets to regulate p38 may also be gained from bacterial systems and natural products. Virulence factors can effectively subvert immune detection by manipulation of cellular signaling pathways. For example, YopJ from *Yersinia* catalyzes the acetylation of serine/threonine residues in MAP2K activation loops, thereby preventing phosphorylation and activation by MAP3K and activation of downstream substrates. The bacterial proteins themselves may be useful templates for therapeutic design as well as the process of acetylation of phosphorylated residues [236, 237]. Resveratrol, tangeretin, and ligustilide are natural products of wine, citrus peels, and ginseng that are natural inhibitors of SAPK/MAPK [238–240]. In addition, inflammatory cytokines TNF-α, IL-1β, IL-6, Th1 cytokines IFNγ, and IL-12, and phosphorylation of JNK and p38 were reduced in LPS-stimulated human peripheral blood mononuclear cells treated with crude and pure extracts from the plant *Boswellia serrata* [241]. These are examples of natural products that could be templates for small-molecule pan- or isoform-specific inhibitors of p38 [238–243]. Paul et al. describe in situ chemical modeling approaches

for the design of such products of natural origin that inhibit TNF-α signaling and MAPK signaling [244]. These natural inhibitors were then analyzed in silico for cell surface properties and computational prediction of in vivo absorption, distribution, metabolism, excretion, and toxicity in order to determine which compounds would be suitable as drug candidates [206]. Other natural and endogenous products such as host defense peptides are known to act on MAPK to suppress LPS-induced release of pro-inflammatory mediators while still protecting rodents from infection [245].

### 4.3 Biological Considerations

Effective inhibition at the molecular level must translate to effective inhibition in vitro and in vivo of cellular and physiological activities. Construction of specific inhibitors based on solid structural designs may still be prone to failure in the clinical setting. This may reflect gaps in our understanding of p38 biology compared with the highly advanced understanding of p38 on a molecular level. These disparate levels of understanding constitute a somewhat unharmonious situation when both are required for the rational design of a therapeutic agent.

As undesirable pharmacological activities of p38 are a formidable concern in the clinical applicability of p38 inhibitors, it would be ideal to understand the impact of p38 on all aspects of inflammation and immunity in advance. Particular attention should be devoted to understanding the biological processes that p38 controls, the mechanisms by which p38 regulates posttranscriptional control of protein expression and a clear delineation of the signaling pathways and role(s) of each of the isoforms in human disease. Complications associated with isoform-specific effects have become a greater concern as accumulating evidence suggests that the isoforms have different physiological roles. At present, the impact of p38γ on inflammatory disease has been somewhat ignored, even though this isoform is highly expressed in tissues and cells of the immune system that are responsible for the production of inflammatory mediators that drive disease. p38α and p38γ are the dominant isoforms found in inflamed RA joints [246]. A number of new in situ molecular modeling approaches are being utilized to develop highly specific inhibitors for the various isoforms of p38 [247, 248]. Based on the discovery that mutations in the hydrophobic core of p38 (Tyr69, Phe327, and Trp337) can create a constitutively active enzyme [235], Askari et al. mutated aspartic acid residues in the activation loop of p38 (Asp176 in p38α, β, δ and Asp179 in p38γ) to produce autoactivated p38 isoforms. Using the constructs, they demonstrated that AP-1-mediated transcription was stimulated by p38α but inhibited by p38γ [248]. These constructs will be extremely valuable tools for the dissection of p38 isoform-specific signal transduction and physiological roles attributed to each isoform.

Considerable work is necessary to discover the biological consequences of suppressing the p38 cellular pathway. Afflicted systems include those whose function depends on normal p38 function and/or the presence of mediators regulated by p38. Both glucocorticoids and anti-TNF-α therapy compromise human defense. Data suggests that p38 plays an important role in the activation of lymphocytes, thus it is reasonable to predict that inhibition of p38 in vivo would compromise innate and cell-mediated immunity [249]. Indeed the p38 MAPK pathway is important in the clonal expansion of lymphocytes [58]. CD28-, IL-2-, or IL-7-dependent T-cell proliferation and IL-2 production can be inhibited by SB203580 [250, 251]. Mice deficient in MKP5/DUSP10 had enhanced levels of pro-inflammatory cytokines during innate immune responses and exhibited greater T-cell activation [252–254]. p38 can also influence the expression of T-cell polarizing cytokines. CSAID SB203580 inhibited IFNγ production by Th1 cells and overexpression of dominant negative p38 impaired Th1 responses. Likewise, mice deficient in MKK3 or MKP1 were defective in IL-12 and IFNγ production [150, 255]. MKP1–/– mice succumb to challenge by both gram-positive and gram-negative microorganisms [150, 152]. p38α is also required for the expression of chemokines and chemotactic agents such as MCP-1, MIP-1α, MIP-1β, and IP10 as well as the cellular response (of T cells, monocytes, macrophages, and neutrophils) to MCP-1, MIP-1α, MIP-1β, RANTES, and fMLP. The expression of chemokines (MCP-1, MIP-1α, MIP-1β, IP10) was blocked in p38α+/– mice, resulting in inhibition of monocyte, neutrophil, and eosinophil infiltration. While this reduced ear swelling in a model of contact hypersensitivity [132], the same suppressive effects would also hamper immune responses to infection. While there was a small decrease in antibody response to antigen challenge, Badger et al. reported no other immunosuppressive effects of the p38 inhibitor in vitro or in vivo despite the potent anti-inflammatory activity [141]. Furthermore chimeric mice with p38α-deficient ES cell-derived lymphocytes have no developmental defect and responded to antigen and antibody [123]. These data suggest that perhaps specific inhibition of the p38α isoforms may not have negative effects on lymphocyte activity. Nevertheless, a thorough investigation into immune defense should be conducted and should involve multiple cell types as inhibition of p38 signaling will have differential effects in different immune cells.

Other potential systems that are prone to negative effects of p38 inhibition include reproduction and

development, coagulation and endothelial function, skeletal muscle function, hematopoiesis, central and peripheral nervous system function, and liver function [256]. p38 inhibitors have caused hepatotoxicity, CNS toxicity, cardiotoxicity, skin rashes, gastrointestinal (GI) tract symptoms, and increased the risk of infection. It will be important to explore approaches to investigate and predict adverse side effects and to determine whether these side effects are related to the target or to the compound. Investigation to achieve this would encompass detailed biochemical characterizations and systems biology approaches [257, 258]. The p38$\alpha^{ki/ki}$ mouse constructed by O'Keefe et al. may be useful for distinguishing between on- and off-target effects of p38α inhibitors as off-target effects of inhibitors would cause toxicity in both wild-type and knock-in mice [146]. Equally important, particular organ systems should be flagged and carefully monitored for toxicity when new drugs enter the clinic. This is particularly important when treating a chronic condition that requires lifetime therapy.

## 5 CONCLUDING REMARKS

Inflammation is a complex process controlled by numerous positive and negative regulators. The p38 MAP kinase pathway is integral to the production of mediators that drive inflammation and pain and the cellular responses to these mediators. If not properly controlled, it can cause dire effects in the inflammatory, immune, and nervous systems that manifest in the development of chronic pain and inflammatory disease. Early inhibitory compounds of p38 demonstrated significant clinical efficacy and served as proof of principle that p38 is an excellent anti-inflammatory therapeutic target. However, these inhibitors were also beset with undesirable off-target toxic effects. Newer versions of these molecular inhibitors must be designed in a manner that is more mindful of the complexity of p38 and the inflammatory response to reach their potential as an effective anti-inflammatory and analgesic therapy.

## 1 INTRODUCTION

Cardiovascular disease has topped the list of killer diseases every year since 1900 (except during the influenza epidemic of 1918) [1]. According to the American Heart Association, one American dies from cardiovascular disease every 36 seconds and nearly 80 million Americans currently have some form of cardiovascular disease. These diseases are costing Americans more than $430 billion a year. However, remarkable progress has been made in the field of cardiology. The development of new drug treatments has helped cut death rates from cardiovascular disease by almost half since 1950. Drug discovery is vital in maintaining this momentum. There are currently over 250 drugs in development for treating heart disease and stroke.

There are many interesting stories in the development of cardiovascular drugs. In 1785, William Withering made the chance observation of the improvement in a patient with severe heart failure after ingesting an herbal remedy [2]. He went on to identify the active ingredient in this remedy to be extracts from the foxglove plant. Over the ensuing 9 years he carefully tried out different preparations from various parts of the plant and documented 156 cases where he described the effects and the best way of using it. He believed that digitalis had a diuretic effect in patients with a weak and irregular pulse. Withering had no real insight into the pharmacologic and physiologic effects of digitalis, and it was actually the courting of his wife that enticed him to advance his expertise in botany that allowed him to make such an observation that inspired the development of digoxin.

The discovery of warfarin is linked to an observation made in the early 1920s of cattle in the northern United States and Canada that would die of uncontrollable bleeding from very minor injuries [3]. It was determined that the cattle were ingesting moldy silage made from sweet clover that functioned as a potent anticoagulant by reducing the amount of functioning prothrombin. The anticoagulant substance in moldy sweet clover was determined to be the coumarin derivative, 4-hydroxycoumarin. Over the next few years, numerous similar chemicals were developed that had the same anticoagulant properties, which eventually resulted in the development of warfarin in 1948. Warfarin was first registered for use as a rodenticide in the United States in 1952 and in 1954 was approved for medical use in humans.

Today cardiovascular drug development depends less on chance observations and more on logical scientific approaches. Most cardiovascular drugs used today were developed using the process known as "forward pharmacology" [4]. This approach begins by taking a pathophysiological or physiological process and carefully examining the role of individual mediators in that process in a disease. This leads to the characterization of entities responsible for a biological activity and to the identification of specific drug targets such as a receptor or enzyme. This process can be inefficient. The concept of the rennin–angiotensin–aldosterone system (RAAS) was first hypothesized in the 1930s. It took almost

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad

four decades before the therapeutic significance of angiotensin-converting enzymes (ACEs) became apparent and an inhibitor of the enzyme was developed. Nearly 50 years after the initial work had been done on the RAAS, captopril (Capoten) reached the market [5]. The development of beta-blockers has a similar story. Approximately 60 years after the characterization of the parasympathetic and sympathetic nervous systems, the beta-blockers became available for human use. In this day and age 50–60 years is not an acceptable amount of time to bring a product to market.

The approach to cardiovascular target identification has changed since the advent of the Human Genome Project. Use of the human genome has allowed for the formation of private and proprietary deoxyribonucleic acid (DNA) databases from which novel cardiovascular drug targets can be identified [6]. Our current pharmacological therapies are directed toward <500 human proteins, but thousands of potential targets are estimated to exist [7]. Exploring the human genome has resulted in the identification of numerous novel drug targets, some of which were identified before anything was known about their biological significance [6]. This is in absolute contrast to the forward pharmacology method used to develop ACE inhibitors and beta-blockers.

New drugs can be designed to take advantage of the deficiencies of the previously developed drugs in order to provide more efficacious and safer pharmacotherapeutic options. For instance, there may be drugs already available to clinicians that are known to affect a previously established drug target. The low-molecular-weight heparins (LMWHs), for example, were developed to take advantage of the limitations associated with unfractionated heparin (UFH). UFH use is accompanied with unreliable pharmacokinetics imposing the need for diligent monitoring and an anticoagulant effect that is modified by platelets, fibrin, vascular surfaces, and plasma proteins. LMWHs are derived through depolymerization of UFH to yield an average fragment size that is approximately one-third the molecular weight. Like UFH, LMWHs continued to produce their anticoagulant effect by activating antithrombin; however, the reduction in fragment size resulted in superior pharmacokinetics, a more predictable response, and more convenient dosing. There are also numerous examples of extended-release formulations and two drug combinations that have been developed from previously launched drugs that allow for more convenient dosing. Additionally, active metabolites derived from prodrugs have been formulated to increase efficacy and eliminate drug interactions. Although improving our current pharmacotherapeutic options is important, an emphasis should be to discover new therapeutic drug targets. The focus of this chapter is to explore current and novel pharmacological therapies in development for the treatment of cardiovascular diseases.

## 2 CORONARY ARTERY DISEASE

### 2.1 Antianginal Agents

Coronary artery disease (CAD) is the leading cause of death of adults in the United States. Death rates are two to three times higher in men than women; however, when compared to death rates prior to 1975, Cardiovascular (CV) death has fallen in most developed countries by 24–50%. Approximately one-half of this reduction is due to improvement in the risk factors of CAD, including reduction in cholesterol levels, blood pressure, smoking, and physical inactivity. The other half is due to improved secondary prevention measures after coronary events, better initial and long-term treatment of acute coronary syndrome, congestive heart failure, and better revascularization procedures [8].

In addition, in-hospital and long-term mortality rates following myocardial infarction have fallen substantially with improvement in medical therapy. This has been noted in the Atherosclerosis Risk In Communities (ARIC) study [9] as well as the National Registry of Myocardial Infarctions (NRMI) registry [10].

Even with improvements in medical therapy and revascularization, including coronary artery bypass surgery and percutaneous coronary intervention, there continues to be patients with angina refractory to all these treatments. Such patients are a challenge to treat and are the rational for novel therapeutic strategies. These strategies include but are not limited to inhibition of fatty acid oxidation, ischemic preconditioning, endothelin receptor blockers, and therapeutic angiogenesis.

The conventional treatment of CAD includes a wide variety of agents, including beta-blockers, nitrates, calcium channel blockers, antiplatelet agents, lipid-lowering drugs, and others. Discussing all these agents is beyond the scope of this chapter, but we will briefly touch on some.

***Beta-Blockers*** Beta-blockers are first-line therapy for angina. Their mechanism of action involves competitive inhibition of catecholamines from binding to the beta-adrenergic receptors. These receptors increase in density after chronic beta-blocker use and thus sudden withdrawal of the medications results in transient supersensitivity to catecholamines, which may precipitate angina, myocardial infraction (MI), or death.

The cardiovascular effects of beta-blockers are mediated by their ability to decrease myocardial oxygen demand. This is achieved by decreasing heart rate, con-

tractility, and left ventricular wall stress by dropping the systemic blood pressure. Cardioselective beta-blockers that mediate their effect by preferentially blocking the beta-1 receptor can decrease unwanted side effects but their selectivity is lost at high doses [11–13].

***Nitrates*** Nitroglycerin was the first medication used in 1879 by Williams Murrell for the treatment of angina pectoris. The mechanism of action works by relaxing smooth muscle cells, causing dilatation of veins of arteries including coronary arteries. This action is mediated via the formation of nitric oxide and subsequent activation of guanylate cyclase and the generation of cyclic guanosine monophosphate (cGMP). Their primary action is venodilatation, causing a decrease in left ventricular end diastolic pressure, resulting in decreased wall stress and decrease myocardial oxygen demand. The clinical effect of direct coronary vasodilation is uncertain, especially in patients with flow-limiting lesions of a coronary artery, which by itself causes maximal vasodilation during ischemia.

A major problem with nitrates is the development of tolerance after chronic usage. The mechanism of tolerance is due to at least the following:

- Impaired bioconversion and formation of nitric oxide
- Reduced bioactivity of nitric oxide
- Activation of the vasoconstrictor renin–angiotensin–aldosterone and sympathetic nervous system in response to nitrate-induced vasodilation

Nitrate tolerance can be presented by intermittent therapy with an adequate nitrate-free period [14–16].

***Statins*** The discovery of the key cholesterol synthesis enzyme 3-hydroxy-3-methylglutaryl coenzyme A reductase and subsequently its inhibitors (statins or HMG-CoA inhibitors) ranks as one of the most important advances of the twentieth century in the prevention of morbidity and death from atherosclerosis. Pleiotropic effects of statins may exist, but the effectiveness of statins in preventing major cardiovascular events in direct proportion to low-density lipoprotein (LDL) cholesterol reduction is well established.

Statins reduce LDL cholesterol from 15 to 60%; have variable effects on total high-density lipoprotein (HDL) cholesterol, raising it 0–15% and reducing triglycerides by 5–30%. Many disingenuous trials compare different formulations and starting doses, attempting to establish that a particular product is better at achieving National Cholesteral Eduction Program (NCEP) goals. Clinical practice should be based on those tested in clinical trials with clinical outcome data.

Rhabdomyolysis is seen in less than 1 : 1000 and when seen is usually in those with coexisting organ dysfunction or those on combination therapy with other hyperlipidemia drugs. Minor muscle pain may be more frequent. The supplement coenzyme Q10 has been used, but it remains of unproven benefit or safety. Transaminitis occurs in 0.1–2% of patients, typically in proportion to potency. Transaminase levels should be measured prior to therapy and then at 12 weeks. The long-term risk of transaminitis is unclear, but if levels remain >3 times upper limit of normal, then statin therapy should be withheld. Once levels return to normal, a different and/or lower dose statin may be tried.

Special care is required when using combination therapy of fibrates and statins. Definite need should be documented and then therapy started at low doses with avoidance of maximum doses of either agent. Future or ongoing trials may determine how low to go with LDL and whether other markers such as C-reactive protein should be measured to determine if maximal benefit is being obtained.

***Ranolazine*** Ranolazine recently became the first novel antianginal medication made available in over 20 years. The most important mechanism of action of ranolazine is decreasing diastolic tension by preventing calcium overload in ischemic myocytes. Its efficacy has been extensively tested especially in patients with chronic stable angina. It is effective for angina relief and significantly increases symptom-limited exercise duration and time to onset of angina. However, ranolazine failed to show any benefit when used in patients with acute coronary syndromes.

A dose-dependant QTc prolongation is an important adverse effect of this medication. However, torsades de pointes has not been reported with ranolazine and, in fact, ranolazine has been shown to have antiarrhythmic traits [17–19].

Multiple newer therapies for CAD and angina pectoris are being developed. Table 1 summarizes some of these medications and their mechanism of action [20].

Another novel therapeutic option for patients with end-stage angina and even peripheral arterial disease is angiogenesis. The goal of this therapy is the induction of new coronary arterial vessels that can effectively provide blood supply to an ischemic area of the myocardium. A number of angiogenic growth factors stimulate blood vessel growth. These include fibroblast growth factors (FGFs), vascular endothelial growth factors (VEGFs), and platelet-derived growth factors (PDEGF) [21].

The experience with these agents is still actively growing, and solutions to many problems are not completely resolved. These problems include patient

**TABLE 1 Novel Therapeutic Agents for the Treatment of Angina**

| Medication | Mechanism of Action |
|---|---|
| Trimetazidine and perihexiline | Inhibition of fatty acid oxidation that increases cardiac metabolic efficency |
| Nicorandil | Potassium channel activator that causes arterial and venous dilatation and mimics a natural process of ischemic preconditioning |
| Ivabradine | Inhibition of a specific sinus node current causing a decreased heart rate |
| Fasudil | Inhibits Rho kinase involvement in vascular smooth muscle contractile response |
| Testosterone | Improves endothelial dysfunction |

selection, mechanisim of delivery of the growth factors, and protein vs. gene therapy. In addition, there are a number of complications associated with this treatment, including but not limited to:

Angiogenesis in nontarget tissues
Increased vascular permeability
Uncontrolled neoplasm growth

### 2.2 Antiplatelet Agents

One of the main goals in CAD treatment is to prevent adverse outcomes from disease. Platelets play a central role in the development of atherosclerosis and clinical expression of thrombotic events. The use of antiplatelet agents has resulted in significant improvements in cardiovascular morbidity and mortality. Antiplatelet therapies, such as aspirin, clopidogrel, and the G-protein (GP) IIb/IIIa receptor inhibitors, are central to the treatment of patients with acute coronary syndrome (ACS). Despite their proven efficacy, many patients receiving these therapies continue to experience major coronary adverse events, or, on the other side of the spectrum, patients receiving these therapies experience major bleeding episodes that have severe consequences on morbidity and mortality. Thus, there is a need to investigate new antiplatelet agents that could potentially offer patients improved safety and efficacy. There are many novel antiplatelet targets in a wide range of developmental stages being investigated for therapeutic benefit in coronary artery disease.

Aspirin exerts its antiplatelet effects by inhibiting the cyclooxygenase-1 (COX-1) enzyme, which limits the production of the potent platelet agonist and vasoconstrictor, thromboxane ($TXA_2$). However, beneficial prostanoids are also produced via the COX-1 enzyme. Therefore, efforts to more specifically block $TXA_2$ may prove fruitful. Several $TXA_2$ receptor antagonists have entered clinical development in recent years. These include ifetroban, sulotroban, and GR32191. Despite the demonstration of antithrombotic effects of these agents in animal studies, phase II/III clinical trials have yielded disappointing results, which has forced development discontinuation of many of these agents. Terutroban is a $TXA_2$ receptor antagonist that exerts antiplatelet effects similar in magnitude to clopidogrel and superior to aspirin under low and high sheer conditions. This drug is now in phase III trials in stroke patients.

Dually acting agents that inhibit $TXA_2$ synthase and antagonize the $TXA_2$ receptor have shown promise in humans. These agents have been shown to reduce platelet aggregation and $TXA_2$ generation. Ridogrel failed to improve coronary flow in the setting of acute myocardial infarction compared to aspirin [22]. Terbogrel showed no benefit in the treatment of primary pulmonary hypertension [23]. Picotamide significantly reduced overall mortality compared to aspirin in diabetic patients with peripheral artery disease with a lower incidence of bleeding [24].

The P2Y12 receptor is predominantly located on platelets and promotes platelet activation through signal activation by adenosine diphosphate (ADP). Ticlopidine and clopidogrel represent the first- and second-generation P2Y12 receptor antagonists, respectively. Due to their limitations, however, other P2Y12 receptor antagonists, both oral and intravenous, are being evaluated for the treatment of patients with atherothrombotic disease. These include prasugrel, a thienopyridine; cangrelor, an adenosine triphosphate (ATP) analog; and ticagrelor, a cyclopentyl-triazolo-pyrimidine (CPTP), all of which have entered phase III development.

Prasugrel differs from the other irreversible thienopyridine P2Y12 receptor antagonists by having an ester group close to the reactive thiol group and a fluorine atom replacing the chlorine atom. Like clopidogrel, prasugrel is a prodrug that requires hepatic metabolism to form its active metabolite, which irreversibly inhibits the P2Y12 receptor [25]. However, the active metabolite of prasugrel is generated more efficiently and at higher concentrations compared with clopidogrel [26]. As a result prasugrel has shown to improve inhibition of ADP-induced platelet aggregation and fewer nonresponders, as measured by inhibition of platelet aggregation [27].

Reversible P2Y12 receptor antagonists, such as cangrelor and AZD6140, have chemical structures that differ substantially from those of the thienopyridines. Cangrelor is an ATP analog characterized by the pres-

ence of substituents in the 2-position of the adenine ring that increase the P2Y12 receptor affinity properties and β,γ-methylene substitutions in the triphosphate part of the molecule that increases the metabolic stability [28]. Cangrelor is administered intravenously and does not require metabolism for therapeutic activity, thus inhibiting platelet aggregation with rapid onset and offset of action, offering potential benefits over clopidogrel [28].

AZD6140 is an oral antagonist of the P2Y12 receptor that does not require metabolic activation [28]. The drug belongs to the same family as cangrelor of stable ATP analogs with high P2Y12 receptor affinity. AZD6140 is less potent than cangrelor but has a rapid onset of action (2–4 h) and a half-life of approximately 12 h [28]. As such, it is the first rapidly acting, reversible oral P2Y12 receptor antagonist in development for the treatment of ACS.

Thrombin is believed to be the most powerful platelet agonist known [29]. It plays a key role in coagulation and hemostasis partially through platelet activation via stimulation of protease-activated receptors (PAR) on the platelet surface. PAR1 and PAR4 are expressed on the surface of human platelets, with the PAR1 receptor proposed as the principal thrombin receptor [30]. Blocking PAR4 has little effect on inhibiting platelet aggregation [31]. Inhibiting the actions of thrombin on platelets by targeting PAR1 receptors is a potential antiplatelet therapy. At least two oral PAR1 receptor antagonists are currently in development: vorapaxar and atopaxar. Pepducins are cell-penetrating peptides that bypass the PAR receptors and modulate thrombin/PAR-induced intracellular signaling [32]. An anti-PAR4 pepducin has been shown to reduce platelet aggregation. This is a novel mechanism for inhibiting receptor function outside of the standard receptor antagonists and antibodies.

Phosphoinositide 3-kinase (PI3K) p110β is important in modulating intracellular calcium flux and GPIIb\IIIa bond stability [33]. PI3K p110β is predominantly required for sustained platelet aggregation under high shear conditions. TGX-221 is an inhibitor of PI3K p110β that has been shown, in animal studies, to inhibit platelet aggregation in vitro and in vivo under high sheer conditions [34]. Administration of TGX-221 caused no changes in bleeding times even at high doses [33].

The binding of von Willebrand factor (VWF) to subendothelial GPIb receptors is required for platelet blinding to injured vasculature [35]. Blockade of this interaction is a potential mechanism to inhibit platelet adhesion and subsequent platelet activation upstream of aggregation [35]. There are several approaches under investigation that target this interaction. A monoclonal antibody directed at GPIb successfully inhibited platelet aggregation and reduced thrombosis [36]. However, it also decreased platelet formation, causing an immediate and irreversible thrombocytopenia. There are two GPIb antagonists derived from snake venoms, crotalin and mamushigin. Crotalin was shown to decrease thrombus formation but was also shown to increase bleeding [37]. Mamushigin reduced aggregation at high sheer stress but stimulated aggregation at low sheer stress [38]. Rather than blocking the receptor another approach is to interfere with the interaction at the level of VWF. The VWF antibody, AJvW-2, was shown to inhibit platelet aggregation and thrombus formation in hamsters and guinea pigs without increasing bleeding times [39]. Aurin tricarboxylic acid binds to VWF, preventing the interaction between GPIb and VWF [40]. In a rabbit model, aurin tricarboxylic acid was more effective at inhibiting thrombus formation than a thromboxane synthase/thromboxane receptor blocker, a GPIIb/IIIa antagonist, and an antibody against tissue factor [40]. Finally, a recombinant VWF peptide, VCL, is able to block the GPIb–VWF interaction [41, 42]. Recombinant vWF fragment Leu504-Ser728 (VCL) does not directly antagonize GPIb or VWF but rather saturates the GPIb receptor to block the interaction. The peptide was shown to reduce aggregation and thrombus formation in primate and guinea pig models.

Leptin is increased in obesity and has been shown to enhance platelet aggregation through the effect of leptin receptors on the platelet surface [43]. Obese individuals may benefit from a leptin receptor antagonist.

The Arp 2/3 complex regulates the shape change platelets undergo upon activation [44]. The shape change is characterized by the formation of filopodia, lamelipodia, stress fibers, and contractile rings. This process is necessary for stable platelet aggregation to occur. Pretreatment with recombinant Arp was shown to arrest the platelets in the early rounded stage of activation while keeping other critical platelet functions intact [44].

Adenosine triphosphate diphosphohydrase (ATPase) or CD39 (Cluster of Differentiation 39) is an enzyme that does not act directly on the platelet but is a dominant contributor to the hydrolysis of the platelet agonists ADP and ATP [45, 46]. The enzyme prevents prothrombotic platelet activation and mitigates excessive platelet recruitment to a growing thrombus. Due to its enzymatic activity, a recombinant soluble CD39 was able to inhibit platelet aggregation in mice. Also using a recombinant ATPase in mice altered to have 100-fold increased ATPase activity, platelet aggregation was reduced and existing platelet aggregates were dissolved.

The CD40/CD40 ligand system is a transmembrane protein that plays an important role in inflammation [47]. The CD40 ligand is shed as a result of platelet

activation and increases production of chemokines, E-selection, vascular cell adhesion protein (VCAM), and intercellular adhesion molecule (ICAM) triggering leukocyte recruitment. Decreasing CD40 ligand shedding or blocking ligand–receptor interaction represents a novel therapeutic approach.

RANTES (Regulated upon Activation, Normal T Cell Expressed and Presumably Secreted) is a chemokine that interacts with P-selectin and mediates monocyte/macrophage infiltration into atherosclerotic lesions [48, 49]. The peptide antagonist Met-RANTES reduced macrophage infiltration in areas of atherosclerosis and decreased neointima formation in mice.

The development of a platelet plug begins when platelets adhere to the site of vascular injury via interactions with subendothelial collagen. Platelets interact with collagen either directly, through glycoprotein VI (GPVI), or indirectly, through VWF. C1q-TNF-related protein-1 (CTRP-1) is an endogenous inhibitor of collagen-induced platelet aggregation [50]. CTRP-1 blocks collagen-dependent platelet function predominantly through the disruption of the interaction between VWF and collagen. CTRP-1 has been shown to prevent platelet thrombosis in vivo in nonhuman primates. CTRP-1 prevents collagen-induced platelet aggregation by specific blockade of VWF binding to collagen.

### 2.3 Conclusion

The biology of coronary artery disease is becoming very advanced. Although many of the targets are rudimentary in development, the number of potential treatment options for the disease is substantial. A topic not focused on in this chapter but that warrants mention is the area of CAD prevention. Therapies targeted at obesity, diabetes, hypertension, and metabolic syndrome are important in preventing the onset of CAD.

## 3 HEART FAILURE

Heart failure is a complex clinical syndrome that results from any structural or functional cardiac disorder that impairs the ability of the heart to fill with or pump a sufficient amount of blood through the body [51]. The prevalence of the disease is reaching epidemic proportions with approximately 5.2 million Americans living with heart failure (HF) [1]. At the age of 40, the lifetime risk of developing HF is 1 in 5. In the last decade there has been a dramatic increase in HF death rate. It is estimated that 80% of men and 70% of women under age 65 who have HF will die within 8 years of diagnosis. HF also imposes a substantial economic burden with an estimated direct and indirect cost of $33.2 billion in the United States for 2007 [1].

Over the past 2 decades, investigators have learned more about the pathophysiologic changes that occur in systolic and diastolic ventricular dysfunction. Expansion of our knowledge of heart failure has increased the gamut of possible targets in HF therapy. However, in comparison with coronary artery disease, the development of HF pharmacotherapeutic options is in its infancy. Although advances have been made in our understanding of the pathogenesis and management of this complex disorder, we are still lacking substantial information regarding fundamental abnormalities, particularly at the cellular level.

The treatment of HF focuses on treating the symptoms and signs of HF and preventing the progression of disease [51]. Drugs that interfere with the excessive activation of RAAS and the adrenergic nervous system improve HF with a depressed ejection fraction (EF) by stabilizing and/or reversing cardiac remodeling. In this regard ACE inhibitors (ACEIs), angiotensin receptor blockers (ARB), and beta-blockers have emerged as cornerstones of modern HF therapy for patients with a reduced EF [51]. Numerous large-scale clinical trials with a wide range of causes and severity of HF have established their importance, and the evidence for the first-line use of these agents is compelling. The advent of neurohormonal active therapies has been a major advance in chronic HF treatment and prevention. However, in the full scope of HF there remain true unmet needs. Currently, there is a paucity of controlled clinical trials concerning the optimal treatment of HF with preserved EF and acute decompensated HF.

### 3.1 Cardiac Remodeling

Heart failure should be viewed as a continuum of developmental stages [51] (Table 2).

A major focus of patients in stages A and B is preventing the progression to stage C or clinical HF. Left ventricular remodeling is a pivotal element is the development of heart failure. Progressive remodeling results in HF and its extent is associated with clinical outcome [52, 53]. A range of cellular and biochemical processes encompass the remodeling process, and each of these processes is a potential therapeutic target.

Cardiac hypertrophy develops in response to elevated wall stress that eventually progresses to failure. At the cellular level multiple signaling pathways interact to drive hypertrophy. Two well-known drivers of cardiac hypertrophy are angiotension II and norepinephrine, which accounts for the utility of RAAS antagonists and beta-blockers in the attenuation of ventricular hypertrophy. Many receptor-activated calcium-dependent and mitogen-activated protein (MAP) kinase-dependent signaling pathways converge toward

**TABLE 2 Stages of Heart Failure**

| HF Stages | Description of Stage | Example of Patient in Stage |
|---|---|---|
| Stage A | High risk for developing HF, but without structural heart disease or symptoms of HF | Patients with diabetes or hypertension |
| Stage B | Structural heart disease but without symptoms of HF | Patients with a previous myocardial infarction (MI) and asymptomatic left ventricular (LV) dysfunction |
| Stage C | Structural heart disease with symptoms of HF | Patients with a previous MI with shortness of breath and fatigue |
| Stage D | Patients with refractory HF | Patients who are awaiting cardiac transplantation |

a final common hypertrophic molecular program regulated by histone deacetylases (HDACs) [54]. Inhibition of HDACs has been shown to attenuate cardiac hypertrophy in animals.

Likewise, Rho-kinase has been identified as one of the effectors of the small guanosine triphosphate (GTP)-binding protein Rho [55]. Accumulating evidence has demonstrated that the Rho/Rho-kinase pathway plays an important role in various cellular functions [55]. Including the pathogenesis of cardiovascular remodeling and hypertrophic development. Fasudil, a clinically available Rho-knase inhibitor, has been shown to inhibit left ventricular hypertrophy after myocardial infarction in mice [56]. There are many other small-molecule inhibitors available that affect a number of hypertrophic pathways. For instance, cyclosporine and rapamycin have been shown to attenuate ventricular hypertrophy [57–60]. However, their lack of cardioselectivity and associated toxicities limits the utility of these agents [61].

A recombinant protein known as periostin has been shown to induce cardiomyocyte proliferation following myocardial infarction, resulting in improved cardiac function. In a rat model of myocardial infarction, this protein, normally expressed during cardiac development, was bound to a biodegradeable extracellular matrix and injected epicardially at the time of injury [62]. Periostin-injected rats had significantly higher proportion of cycling cardiomyocytes and cardiomyocyte nuclei, which translated into improved ventricular remodeling, better myocardial function, and reduced infarct size [62].

### 3.2 Inflammation Targets

Heart failure has been associated with an increase in a range of inflammatory cytokines such as tumor necrosis factor-α (TNF-α) and various interleukins [63]. The potential utility of TNF-α antagonists is based on a correlation between HF severity and plasma TNF-α and the finding that overexpression of cardiac-specific TNF-α results in severe dilated cardiomyopathy [64]. However, the TNF-α antagonist, enterecept, offered negative results in HF patients [65]. Several mechanisms have been proposed for this negative outcome. It may be that accumulation of inflammatory markers is a consequence of HF, but disrupting the inflammatory cascade does not influence the HF process. Reduced renal clearance associated with HF may prevent elimination of the cytokines. Alternatively, these targets may be intimately involved in HF pathophysiology but is much more complex than currently understood. Despite previous failures, there remains a considerable amount of interest in immune modulation as a therapeutic strategy in HF. For instance, intravenous immunoglobin (IVIG), which is used in a number of inflammatory diseases, has been shown to significantly increase ejection fraction in patients with heart failure [66, 67].

### 3.3 Contractile Targets

Failing myocardium is linked with a reduced myocardial contractility triggered by defective handling of intracellular calcium [68]. Key components of intracellular calcium dysregulation include protein kinase A-mediated hyperphosphorylation of the ryanodine receptor, which causes diastolic calcium leak and reduced expression of the sarcoplasmic reticulum $Ca^{2+}$ ATPase (SERCA), which impairs calcium reuptake by the sarcoplasmic reticulum [69]. The ryanodine receptor stabilizer, JTV519, inhibited diastolic calcium leakage and improved contractility [70]. However, intracellular calcium overload can lead to electrical instability putting patients at risk for arrhythmias. Rather than increasing intracellular calcium supplies, another approach is to use the intracellular calcium supplies more efficiently. Levosimendan is classified as a "calcium sensitizer" that stabilizes the molecular conformation of troponin-C when it binds calcium. This improves contractility and has been shown to improve hemodynamics in acute decompensated heart failure [71]. Cardiac myosin activators have also been developed to increase contractility without changing intracellular calcium levels [72].

Another potential inotropic target is the Na/K-ATPase enzyme. Inhibition of Na/K-ATPase has been shown to augment myocardial contractility by

stimulating calcium entry via the sarcolemmal Na/Ca exchanger [73]. Istaroxime is a Na/K-ATPase inhibitor chemically unrelated to digoxin [74]. Preliminary data suggests that istaroxime permits intracellular calcium accumulation while avoiding proarrhythmic consequences. The mechanism behind this is unclear.

### 3.4 Metabolic Modulation

Increasing metabolic efficiency has become another potential target in HF therapy. Metabolism of fatty acids is the main source of ATP production in the heart [75]. Fatty acids are not as efficient as glucose as an energy source requiring more oxygen to produce an equivalent amount of ATP [76]. The heart seems to pump more efficiently if the fuel is glucose. There is evidence that enhancement of glucose oxidation in heart failure increases cardiac contractility and that reliance on fatty acid oxidation in heart failure may contribute to systolic dysfunction. Cardiac metabolic agents switch metabolism from fatty acid oxidation to glucose oxidation for more efficient ATP generation. Perhexiline, a carnitine palmitoyl transferase-1 (CPT-1) inhibitor, and trimetazidine, an inhibitor of mitochondrial fatty acid B-oxidation, long-chain 3-ketoacyl coenzyme A thiolase, are two of a number of drugs that may act in this way. Both drugs have shown favorable effects in HF thus far [77]. In patients with HF, perhexiline improved peak exercise oxygen consumption, left ventricular ejection fraction, HF symptoms, resting and peak stress myocardial function, and skeletal muscle energetics [78]. Treatment with trimetazidine, for 18 months, was associated with improvements in New York Heart Association (NYHA) functional class, left ventricular ejection fraction, and other indices of cardiac remodeling [79].

### 3.5 Neurohormonal Targets

Activation of endogenous neurohormonal systems plays a major role in the progression of HF. Neurohormonal factors such as angiotensin II, norepinephrine, aldosterone, endothelin, and vasopressin adversely affect the structure and function of the heart. They work in concert to increase hemodynamic stress by causing sodium retention and peripheral vasoconstriction and exert direct toxic effects on the myocardium. In HF, there are many successful treatment options that antagonize neurohormonal pathways and our growing knowledge of these pathways has produced a number of potential therapeutic targets.

The RAAS plays an important role in the pathophysiology of HF, and inhibition of the RAAS has become a target for several cardiovascular drugs [80]. ACEIs are the best studied drugs in this class [81, 82]. However, concern regarding incomplete inhibition of the RAAS with ACEIs has led to the use of newer agents such as ACEIs and aldosterone antagonists that when added to ACEIs provide more complete inhibition of the RAAS.

Renin blockade may provide superior neurohormonal inhibition by blocking the system upstream rather than downstream like ACE inhibitors and ARB [83]. Upstream blockade avoids reflex activation of renin, angiotensin I, and angiotensin II; however, this may also diminish the potential beneficial effects seen from angiotensin II activation of the angiotensin subtype $AT_2$ receptor [84]. The direct renin inhibitor, aliskiren, is approved in the United States for the treatment of hypertension and will be extensively studied in the HF population [83]. There are also other renin inhibitors currently under development.

Vasopressin is critical in the regulation of fluid balance, vascular tone, and may play a role in myocardial remodeling [85]. The vasopressin system comprises $V1_A$ receptors, which primarily mediate vasoconstriction, and $V_2$ receptors, which promote free water reabsorption [86]. Vasopressin antagonists, tolvaptan and conivaptan, are undergoing clinical development for the treatment of HF. Tolvaptan is a selective $V_2$ antagonist that significantly promoted diuresis but thus far has not been shown to reduce major HF-endpoints such as cardiovascular mortality or HF-related hospitalizations [87, 88]. In addition to tolvaptan, other selective $V_2$ antagonists are under development [85, 89]. Conivaptan provides simultaneous blockade of $V1_A$ and $V_2$ receptors and has been shown to improve select parameters of cardiac performance [85, 90, 91]. Nonselective vasopressin blockade is theoretically advantageous; however, it is unclear whether it will confer greater clinical benefit.

Urodilatin is an endogenous peptide released by the kidney in response to atrial stretch that regulates renal sodium and water excretion [92]. Its syntheic equivalent, ularitide, demonstrated enhanced diuresis and hemodynamic improvements in acute decompensated HF patients [93].

Adrenomedullin is an endogenous vasorelaxing and natriuretic peptide that plays an important role in cardiorenal regulation [94]. Based on its vasodilatory and antifibrotic actions, it is thought that adrenomodullin may potentially have a therapeutic effect on heart failure and renal failure. The administration of adrenomedullin has been shown to result in hemodynamic and renal benefits when added to traditional therapies [95, 96].

The peptide, urotensin II, is regarded as the most potent vasoconstrictor described and may be contributory to increased vascular tone in HF patients [97].

Increased gene expression of the ligand and the receptor has been observed in failing myocardium of HF patients [98]. Urotensin II receptor blockers have been developed and may be a potential therapeutic option in HF [99].

### 3.6 Conclusion

The potential therapies listed in this chapter are not all-inclusive, illustrating that great progress is being made in the identification of novel pharmacological targets in HF. However, the pace that therapies move toward clinical use is slow. It has been estimated that the cost of conducting a large-scale HF trial ranges between $102 and $207 million, and recent development failures have discouraged the industry from investing large amounts of money to develop an HF drug in a broad population [100].

**TABLE 3 Vaughan Williams Classification**

| Class | Drugs | Mechanism of Action |
|---|---|---|
| Ia | Quinidine<br>Procainamide<br>Disopyramide | Block $Na^+$ channels<br>Intermediate onset/offset kinetics |
| Ib | Lidocaine<br>Phenytoin<br>Mexilitine | Block $Na^+$ channels<br>Rapid onset/offset kinetics |
| Ic | Flecainide<br>Propafenone | Block $Na^+$ channels<br>Slow onset/offset kinetics |
| II | Beta-Blockers | Antagonize β-Adrenergic receptors |
| III | Amiodarone<br>Sotalol<br>Ibutilide<br>Dofetilide<br>Bretylium | Block-delayed rectifier $K^+$ channels |
| IV | Verapamil<br>Bretylium | Block the L-type $Ca^{2+}$ channels |

## 4 ARRHYTHMIAS

### 4.1 Current Concepts in Pharmacotherapy

The incidence of ventricular and supraventricular arrhythmias has increased dramatically in recent decades. This is due, in part, to the aging of our population and the increasing prevalence of HF and CAD. Accounting for one-third of cardiac rhythm disturbance hospitalizations, atrial fibrillation is estimated to affect 2.3 million people in the United States and 4.5 million in Europe [101]. Over the past two decades hospital admissions due to atrial fibrillation has increased by 66% [101]. Although the failure of discrimination from other arrhythmias has complicated calculations, the estimated prevalence of supraventricular arrhythmias is 6 to 8 per 1000 people [102]. Sudden cardiac death (SCD), mostly from ventricular arrhythmias, has been estimated to be responsible for up to 18.5% of all deaths, accounting for approximately 300,000–350,000 deaths annually [103, 104].

Antiarrhythmic drug therapy has traditionally been the mainstay of treatment for both ventricular and supraventricular arrhythmias. In the past decade, the development of nonpharmacologic therapies, such as targeted ablation of arrhythmogenic tissues and implantable cardiac defibrillators, as well as the limited efficacy and the significant adverse effects of antiarrhythmic agents, has dramatically altered the treatment of cardiac arrhythmias [105]. In addition, recent studies have suggested a diminished need for maintaining normal sinus rhythm in patients with atrial fibrillation. This has led some to question the future of antiarrhythmic drugs. These agents, however, will remain an important complement to nonpharmacologic methods of arrhythmia treatment.

Most antiarrhythmics are ion channel blockers and are classified by their predominate site of action [106] (Table 3). Class I agents are those that block $Na^+$ channels. This class is further divided into three subgroups according to their onset and offset kinetics. β-Adrenergic receptor antagonists or beta-blockers make up class II. Class III agents are $K^+$ channel blockers that block one specific potassium current, termed $I_{Kr}$ (the rapid component of the delayed $K^+$ current). Class IV is made up of agents that block L-type $Ca^{2+}$ channels. Although antiarrhythmic drugs in the same class share important electrophysiologic properties, most drugs block multiple ion channels, which limits the value of the simple Vaughan Williams classification scheme. In addition, in most cases, the choice of antiarrhythmic drug therapy is not mechanism based but rather remains empiric and is made on an individual basis by trial and error and consideration of side effects.

Trials comparing rate and rhythm control strategies in patients with persistent and paroxysmal atrial fibrillation (AF) [107–111] found no reduction in death, disabling stroke, hospitalizations, new arrhythmias, or thromboembolic complications when providing therapy to maintain normal sinus rhythm. These studies show that controlling the ventricular rate with atrioventricular (AV) node blocking agents is just as effective at reducing events as treating patients with antiarrhythmics to maintain normal sinus rhythm on an intention-to-treat basis. Many patients, however, eventually need antiarrhythmic drug therapy to suppress symptoms, improve exercise capacity and hemodynamic function, and prevent tachycardia-induced cardiomyopathy due

to AF. Additionally, further analysis shows that a majority of events in the trials comparing rate and rhythm control strategies occurred while patients were in AF, suggesting that the rhythm "strategy" is not at fault but rather that antiarrhythmic medications are not effective enough at maintaining normal sinus rhythm for a benefit to be seen. Current antiarrhythmic agents will maintain sinus rhythm in 23–79% of patients after 12–21 months of follow-up [112].

Ventricular fibrillation (VF) and ventricular tachycardia (VT) are most commonly the consequence of coronary heart disease [113]. They differ fundamentally from supraventricular tachycardias in that they are a common cause of SCD. No class of antiarrhythmic agent has clearly been demonstrated to reduce total and SCD mortality in patients at risk for SCD [114–117], and as a group the antiarrhythmics have limited efficacy for preventing VT [118, 119]. Their present role is as an adjunct to implantable cardioverter-defibrillator (ICD) implantation to reduce the number of shocks or in patients who do not wish to have an ICD. Sixty to 70% of patients with ICDs implanted for spontaneous VT will have therapy delivered for recurrent VT or VF during follow-up [120]. In addition, 20–25% of patients will have "inappropriate shocks," most commonly for rapid atrial fibrillation. For these reasons, additional therapy is often required for ICD recipients for preventing recurrent arrhythmias and ICD firings following device implantation. When used, empiric amiodarone is usually the drug of choice even though most studies show no clear advantage of amiodarone over placebo. [118, 119]. In addition, chronic administration of amiodarone is associated with complex drug interactions and a host of adverse side effects involving the lung, liver, thyroid, and skin. A number of clinical trials have evaluated the efficacy of class Ia, Ib, Ic, and III drugs in the long-term prevention of ventricular arrhythmias. A consistent message from these trials is that antiarrhythmic drugs may be proarrhythmic, especially in patients with coronary disease [121].

Research focused on improving the understanding of the mechanisms of arrhythmias will allow identification of molecular and cellular targets for new antiarrhythmic treatment options. Electrophysiological studies and molecular cloning have detailed the functional properties of $Na^+$, $Ca^{2+}$, and $K^+$ currents in cardiomyocytes and have demonstrated that distinct molecular entities give rise to the various cardiac ion channels and shape the myocardial action potential. Reconstruction of the critical components of cardiac ion channels will permit the development of more selective and effective antiarrhythmics. These recent advances in our understanding of the molecular and cellular basis of arrhythmias suggest that novel drugs can be developed that modulate not only traditional ion channels ($Na^+$, $Ca^{2+}$, and $K^+$ channels) with less proarrhythmic potential but also new molecular targets such as those involved in disease-associated electrical remodeling [122].

### 4.2 Antiarrhythmics under Development

A number of antiarrhythmic agents are currently under development (Table 4). The list includes agents that are modifications of existing compounds and agents with novel mechanisms of action. Three agents that are advanced in their development are vernakalant, azimilide, and dronedarone.

Vernakalant is an atrial-selective $Na^+$ and $K^+$ channel blocker under development for the acute conversion and chronic treatment of atrial fibrillation [123]. This antiarrhythmic blocks $I_{Kur}$, $I_{to}$, $I_{KAch}$, and I-Na currents allowing it to selectively prolong atrial refractoriness with minimal electrophysiologic or proarrhythmic effect on ventricular tissue.

Reverse-use dependence is a characteristic shared by most class III antiarrhythmics [124]. This is where a drug exerts greater effects at slower heart rates than at faster ones. This characteristic is opposite to what an ideal antiarrhythmic agent would do. An ideal antiarrhythmic would exert its effects at fast rates to interrupt or prevent tachycardias rather than at slow rates where prolongation of refractoriness is more prone to precipitate torsades de pointes. Azimilde is a novel class III antiarrhythmic being developed for the treatment of supraventricular and ventricular arrhythmias that does not exhibit reverse-use dependence [125]. This antiarrhythmic reversibly blocks both the rapid acting component ($I_{kr}$) and slowly acting component ($I_{ks}$) of the delayed rectifier potassium channel ($I_k$) [126]. The most significant adverse effect of azimilide is torsades de pointes, although the fact that it does not exhibit reverse-use dependence makes the occurrence less common with this agent than with other class III medications.

Dronedarone is an antiarrhythmic similar to amiodarone. Like amiodarone, dronedarone is considered a class III antiarrhythmic with its predominant mechanism of action consisting of blockade of $I_{kr}$, $I_{kl}$, $I_{KACh}$, and $I_{SUS}$ channels and with additional effects on $Na^+$ and $Ca^{2+}$ channels [127]. Dronedarone was developed to have a similar efficacy as amiodarone but with an improved safety and tolerability profile [128–130].

### 4.3 Conclusion

With advancing technology in surgical and device therapies, the future management of arrhythmias will most

**TABLE 4 Investigational Antiarrhythmic Drug in Development[a]**

| Modification of Existing Compound | Novel Mechanism Of Action |
|---|---|
| Compound (site of action) | Compound (site of action) |

[a]Abbreviations: β, β-adrenergic antagonist; ICa, inward calcium current; IKach, Ach-sensitive inward potassium current; IKATP, ATP-sensitive inward potassium current; IKI, inward potassium rectifier; IKr, rapid component of the delayed rectifier potassium inward current; IKs, slow component of the delayed rectifier potassium inward current; IKur, ultra-rapid component of the delayed rectifier potassium inward current; INa, inward sodium current; Ito, transient outward potassium current.

*Sources*: Data from refs. 131–133.

likely evolve with even less reliance on antiarrhythmic drugs. However, the development of safer and more efficacious antiarrhythmic drugs remains desirable with several potential agents in the pipeline. In addition, the evolving knowledge about the molecular basis of arrhythmias will continue to provide novel drug targets.

## 5 CONCLUSION

Heart disease is responsible for more deaths than any other disease. Recent advances in pharmacotherapy have helped to lessen the burden of heart disease but new technology is needed to maintain our progress. There are numerous potential cardiovascular therapeutic targets in various stages of development for the treatment of CAD, heart failure, and arrhythmias. With advances in genetics and molecular biology the list will most definitely grow.

# EZETIMIBE AND CHOLESTEROL ABSORPTION

Stefan Oswald and Werner Siegmund
*Department of Clinical Pharmacology, University of Greifswald, Greifswald, Germany*

## 1 INTRODUCTION

Coronary heart disease (CHD) remains the leading cause of morbidity and mortality in the western world. More than the half of atherosclerosis-associated deaths were due to CHD (in the United States: ~450,000 in 2004), which is responsible for 83% of deaths in individuals over 65 years of age [1]. There is convincing evidence from many large epidemiological studies that elevated serum low-density lipoprotein cholesterol (LDL-C) concentrations are associated with an increased risk for the development of atherosclerosis and CHD leading to such potential life-threatening events as myocardial infraction and stroke [2–5].

The pathophysiological mechanisms behind these observations are complex and currently explained with LDL-C oxidation, incorporation of these lipids into macrophages, their conversion to foam cells, and subsequent development of atherosclerotic lesions in the vessel wall, which results in manifold dysfunctions of the endothelium [6].

Recent treatment guidelines such as the Third National Cholesterol Education Program (NCEP) emphasize the need for aggressive LDL-C-lowering therapy in individuals at substantial risk or patients with cardiovascular diseases [7].

For pharmacological intervention several classes of lipid-lowering drugs have been approved in the last two decades, such as hydroxy-methylglutary-coenzyme A (HMG-CoA) reductase inhibitors (statins), fibrates, nicotinic acids, and bile-acid-binding resins. In particular for statins, the most potential and most frequently prescribed of the cholesterol lowering drugs, the benefits of lipid-lowering therapy have been clearly demonstrated in several clinical trials for primary and secondary prevention [8–10]. However, many hypercholesterolemic patients fail to reach the recommended LDL-C target concentrations on statin therapy [11, 12]. Potential reasons include poor patient compliance, insufficient drug response, drug intolerability, as well as inadequate stain dose caused by concerns about safety risks at higher satin doses. With regard to the latter, the relatively high doses of statins required to enhance their cholesterol-lowering effects are connected with the incidence of serious adverse side effects (e.g., myopathy, rhabdomyolysis) [13]. However, even at maximum statin dose titration up to 80 mg, approximately one-third of patients did not achieve the recommended LDL-C levels [14]. Compared to the high LDL-C-lowering potency of 30–40% by low-dose satins (10–20 mg/day), doubling the daily dose only results in an additional cholesterol-lowering benefit of about 5%. Although combining lipid-lowering drugs that act via complementary pathways may provide more pronounced reduction of LDL-C, comedication with available agents may increase the risk for drug interactions or side effects [15]. Specifically, the combination therapy with fibrates was shown to increase the risk of myotoxicity, which caused the worldwide withdrawal of cerivastatin in August 2001 due to numerous deaths [16]. Thus, there was the urgent need for other compounds and principles that would offer supportive strategies.

Accordingly, the demand for additional agents has directed research toward the inhibition of intestinal cholesterol absorption. The rationale for this therapeutic strategy is based on the known positive correlation between the serum LDL-C levels and the efficiency of intestinal cholesterol absorption in humans [17]. Consequently, a 90–100% reduction of intestinal cholesterol absorption achieved a lowering of total serum cholesterol and LDL-C by 35–62% in hypercholesterolemic individuals [18]. With the approval of ezetimibe in the fall of 2002, the first selective inhibitor of intestinal cholesterol absorption became available and has markedly advanced the treatment of hypercholesterolemia.

This chapter will focus on the discovery and development of ezetimibe, its pharmacological and pharmacokinetic properties, as well as its therapeutic implications. Furthermore, the molecular mechanisms of cholesterol absorption, whose understanding was completely revolutionized by ezetimibe-associated research, and novel therapeutic approaches affecting this promising pharmacological mechanism will be highlighted.

## 2 INTESTINAL CHOLESTEROL ABSORPTION

The serum concentration of cholesterol is maintained by a complex and highly regulated balance of endogenous de novo synthesis in the liver, removal and catabolism of lipoproteins from the systemic circulation, biliary secretion of cholesterol and bile acids, as well as intestinal (re-)absorption of bile acids and of dietary and biliary cholesterol [19]. From the current point of view, intestinal cholesterol absorption is a multistep process involving several enzymes and proteins (Fig. 1). The total cholesterol content of an adult human body (70 kg) is about 140 g of which less than 1% is subjected to daily turnover [20]. The biliary secretion of cholesterol into the alimentary canal ranges from 0.5 to 2 g/day of which nearly 50% is reabsorbed. Additionally, the intestinal mucosal cell turnover contributes ~300 mg/day of intraluminal cholesterol. Thus, from the physiological point of view humans do not have a dietary requirement for cholesterol because the body is fully capable to synthesize all the cholesterol that it needs. Nevertheless, a typical western diet delivers 300–500 mg/day of additional cholesterol into the intestinal tract [21]. In humans, cholesterol absorption primarily occurs in the duodenum and proximal jejunum of the small intestine and is characterized by a pronounced interindividual variation (20–80%). Dietary cholesterol intake is usually associated with fat consumption, and digestion and absorption begins in the stomach when lingual and gastric lipases are mixed with chyme and hydrolyze dietary triglycerides. This process continues within the small intestinal lumen, where bile and pancreatic juices are added to the crude emulsion. The juices contain several hydrolytic enzymes, including cholesterol esterase, that hydrolyzes the small portion of dietary cholesterol esters (5–15%) [22]. Under the influence of bile salts, phospholipids, fatty acids, and monoglycerides, mixed micelles are formed in which unesterified cholesterol is incorporated. This step is critical for the enteral absorption of cholesterol due to its nearly water insolubility ($2.3 \times 10^{-6}$ g/L at pH 1–10). Before interaction and subsequent transport of cholesterol molecules across the mucosal cell membrane, an unstirred water layer and an aqueous surface mucous coat, both diffusion barriers that are located at the intestinal lumen–membrane interface, must be passed. This emphasizes the need of bile salts as biologic amphipathic detergents. Plant sterols and stanols as ß-sitosterol and ß-sitostanol are thought to interrupt the formation of these mixed micelles, leading to a significant reduction of cholesterol absorption, which is the rationale behind marketing of plant sterol or stanol-enriched margarines [23].

**Figure 1** Intestinal and hepatic determinants involved in intestinal sterol absorption. Abbreviations: ABC, ATP-binding cassette; ACAT, acyl CoA:cholesterol acyl transferase; $Apo_{48}$, apolipoprotein B48; ASBT, apical sodium-dependent bile salt transporter; BSEP, bile salt exporting pump; C, cholesterol; CE, cholesterol esters; CR, chylomicron remnants; CYP, cytochrome P450 enzyme; ER, endoplasmic reticulum; HMG-CoA, hydroxy-methylglutary-coenzyme A; MTP, microsomal triglyceride transfer protein; NPC1L1, Niemann–Pick C1 like 1; PS, plant sterols; TG, triglycerides.

Thereafter, the micellar fraction undergoes disaggregation at the brush border membrane of the enterocytes. Referring to the following absorption step, it was assumed for decades that lipophilic cholesterol (log $P = 9.83$) undergoes only passive diffusion uptake from the intestinal lumen. There was a significant gap between the knowledge of well-defined cholesterol biosynthesis and clearance pathways and the molecular mechanisms controlling cholesterol absorption in the gut wall, which was supposed to play only a negligible role in overall cholesterol disposition. Contrary to this, there was ample evidence that cholesterol absorption might be facilitated by a certain uptake carrier because (1) cholesterol absorption is characterized by a second-order kinetics, (2) marked differences between the absorption of structure-related plant sterols and cholesterol were detected, (3) the transport process is sensitive to proteases, and (4) small molecules such as neomycin, an aminoglycoside antibiotic, or SCH48461 are capable to interrupt intestinal sterol absorption, whereas the identity of this putative cholesterol transporter remained elusive [20, 23]. Several potential candidates such as the adenosine triphosphate (ATP)-binding cassette (ABC) A1, the scavenger receptor type B1 (SR-B1), the sterol-efflux pumps ABCG5/G8, the annexin-2/caveolin-1 complex, or the aminopeptidase N (CD36) were postulated to be involved in cholesterol uptake. However, none of these variables could be shown to facilitate cholesterol uptake in vivo [24, 25].

In March 2004, Altmann et al. from the Schering-Plough laboratories overcame the paradigm of passive cholesterol absorption by showing that with ezetimibe cholesterol lowering is obviously caused by the inhibition of the Niemann–Pick C 1 like 1 (NPC1L1) protein [26]. NPC1L1 was shown to be mainly expressed in the proximal jejunum, that is, the intestinal site of cholesterol absorption. In this report, it was assessed that NPC1L1 knockout mice showed significantly lowered cholesterol absorption compared to wild-type animals, which was similar to the effects of ezetimibe-treated wild-type mice and resistant to further reduction by ezetimibe. These findings led to the suggestion that NPC1L1 is critical for the intestinal sterol uptake and most likely the molecular target of ezetimibe.

However, cholesterol that enters the enterocytes and that is not effluxed via the half transporters ABCG5/G8 moves to the endoplasmic reticulum, where it is esterified by the acyl CoA:cholesterol acyl transferase (ACAT) 2. It is now well established that ABCG5/G8, which resides on the apical membrane of the enterocytes and prevents sterol accumulation, occurs a higher efflux capacity for plant sterols compared to cholesterol, which is responsible for their poor absorption (5–15%) and their markedly lower serum concentrations in humans [21, 22]. Consistently, mutations in one of these transporter genes leads to the rare hereditary disease of sitosterolemia, which is characterized by hyperabsorption of plant sterols and cholesterol, which accelerates the development of atherosclerosis and premature CHD [27].

In the following event, esterified cholesterol, triglycerides, and apolipoprotein $B_{48}$ (apoB) are assembled to nascent chylomicrons via the microsomal triglyceride transfer protein (MTP) [19, 22]. The importance of MTP activity is clarified by reports of patients with abetalipoproteinemia, a disease caused by *MTP* gene mutations, who exhibit serve steatorrhoea, fatty liver, neurologic symptoms, and only low serum cholesterol levels. Finally, the chylomicrons are delivered into lymph and reach the systemic circulation via the thoracic duct. After the degrading influence of endothelial lipoprotein lipases, the resulting cholesterol-enriched chylomicron remnants are taken up by the liver to be processed to various lipoproteins, which enable cholesterol transport to the periphery to fulfill its numerous physiological functions (e.g., synthesis of bile acids, vitamin D, and steroid hormones) [20, 22]. Figure 1 summarizes the intestinal and hepatic variables involved in cholesterol absorption.

In reference to the intestine, hepatobiliary secretion of sterols is mediated by ABCG5/G8, which initiates an enterohepatic recirculation. Bile salts are predominately excreted into gut lumen via the bile salt exporting pump (BSEP). Cholesterol and bile that escape intestinal reabsorption are excreted with feces as neutral sterols or sterol acids, which represent the major sterol elimination pathway from the body.

Despite that under certain circumstances (e.g., disease, drug therapy) one of the mentioned steps involved in intestinal cholesterol trafficking (e.g., lipase activity, formation of mixed micelles, sterol efflux, esterification) can become rate limiting, the NPC1L1-mediated absorption appears to be the most important and specific step of the sterol absorption machinery without influence on the absorption of other lipids as triglycerides, fatty acids, and lipophilic vitamins.

Beyond the described cascade of enzymes and proteins that mediate in concert the intestinal cholesterol absorption, the whole-body cholesterol homeostasis is controlled by a highly regulated network of nuclear receptors to counteract excessive cholesterol uptake. Thus, in many studies even massive intake of dietary cholesterol caused no concomitant elevation of serum cholesterol, which led some authors to the conclusion that there is no association between dietary cholesterol intake and atherosclerosis [28]. For instance, dietary sterols that are taken up from the intestine undergo cytochrome P450 (CYP) enzyme-mediated

biotransformation to oxysterols, which are strong inducers of the nuclear transcription factor lipid X receptor (LXR), leading to increased expression of intestinal and hepatic ABCG5/G8 and ABCA1 but decreasing levels of HMG-CoA synthetase and reductase as well as NPC1L1 [29, 30]. Thus, cholesterol activates its own intestinal and hepatic kick-out transport by ABCG5/G8 but slows down its intestinal NPC1L1-mediated uptake and its endogenous synthesis. Furthermore, oxysterols activate CYP7A1 (via binding to LXR), which metabolizes cholesterol to bile acids. These degradation products are subjected to active biliary secretion by BSEP. Interestingly, the expression of BSEP is enhanced by bile acids due to activation of the farnesoid X receptor (FXR), which downregulates on the other side CYP7A1 and the ileal bile acid uptake transporter (apical sodium-dependent bile salt transporter, ASBT). Altogether, this elevates cholesterol elimination but also prevents systemic accumulation of cytotoxic bile acids. In contrast to this, inhibition of HMG-CoA reductase by statins was shown to increase the intestinal NPC1L1 expression and cholesterol absorption [31, 32].

Finally, there are several functional feedback mechanisms that control intestinal absorption, endogenous biosynthesis, enzymatic degradation, and active excretion of cholesterol. This regulatory network implies that modulation of one of these steps (e.g., cholesterol synthesis or absorption) will cause compensatory effects that demand the use of combination therapy.

## 3 PHARMACOLOGICAL PRINCIPLE OF CHOLESTEROL ABSORPTION INHIBITION BEFORE EZETIMIBE

Based on the relevance of intestinal cholesterol absorption to the overall body cholesterol homeostasis as described before, drug-mediated blockade of this process appears to be a promising pharmacological approach. Thus, it is expected to reduce the incorporation of cholesterol into chylomicrons, which in turn diminishes the delivery of cholesterol to the liver [23, 33]. The consequences of reduced hepatic cholesterol supply include decreased LDL production, increased LDL clearance, thereby reducing serum cholesterol and, subsequently, may reduced atherogenesis.

Before ezetimibe was introduced to the market, this mechanism was already realized by bile-acid-binding resins. These drugs, including cholstyramine, colestipol, and colesevelam, are not absorbed from the intestine and reduce LDL-C by unspecific binding of biliary secreted bile acids, which interrupts their reabsorption from the ileum and leads to subsequent fecal elimination [23, 33]. This results in depletion of the bile acid pool, which is regenerated by catabolism of serum cholesterol, increased LDL receptor expression, and lowering of serum LDL-C of about 15–20%. Despite their proven reduction of LDL-C and CHD events, however, these compounds are associated with several unpleasant side effects such as constipation, steatorrhoea, bloating, flatulence, and hypovitaminosis, which limit patient compliance. Furthermore, this is encouraged by the relatively high doses that must be consumed for drug efficacy (5–20 g/day). Due to their unspecific binding capacity for anionic and lipophilic compounds, the absorption of many coadministered drugs, including furosemide, L-thyroxine, digoxin, and warfarin, is markedly influenced [34]. Therefore, bile-salt binding resins remain only as compounds of the second choice in cases of insufficient LDL-C lowering by statins or drug intolerance.

Another approach to lower intestinal cholesterol absorption is realized by some functional food products such as low-fat spreads or yogurt drinks containing esters of plant sterols and stanols such as sitosterol, campesterol, or stiostanol (e.g., Benecol, Becel) [21, 35]. Plant sterols, of which sitosterol and campesterol are the most abundant compounds, are naturally present in all vegetable food products and structurally related to cholesterol (campesterol = 24-metyl cholesterol, sitosterol = 24-ethyl cholesterol). They are not synthesized in the human body and exclusively of dietary origin. Their intestinal uptake is facilitated via the same NPC1L1-mediated mechanism as is known for cholesterol. The daily ingestion of plant sterol is comparable to cholesterol (300–500 mg), but the subsequent serum concentrations are usually less than 1% of that of serum cholesterol [21]. This poor intestinal absorption (5–15%) is caused by their high-affinity reverse transport into gut lumen by the intestinal and hepatic sterol efflux pumps ABCG5/G8. The absorption of plant stanols (5α-saturated plant sterols) is considerably lower than that of plant sterols, and these compounds are even more potent in cholesterol absorption inhibition. It is assumed that plant sterols and stanols may inhibit the micellar incorporation of cholesterol within the gut lumen. Hence, the serum LDL-C is reduced at about 10%. Several reports imply that a daily intake of less than 3 g stanols/sterols is capable to reduce significantly the serum cholesterol level [35]. Short-term studies estimated a reduction of CHD by plant sterols/stanols of about 20–25%, whereas no serious side effects were described. Consequently, the U.S. Food and Drug Administration (FDA) have concluded that foods containing plant sterols/stanols may reduce the risk of CHD. On the other side, increased serum levels of plant sterols as caused by enriched dietary products was reported to possibly increase the incidence of CHD [35].

Referring to this, more data are required to prove the long-term safety of these nutritional products. A novel development of plant stanol derivatives represents FM-VP4. This water-soluble agent is a mixture of the ascorbyl phosphate esters of campestanol and sitostanol, which are not absorbable from the gut and very potent inhibitors of the intestinal cholesterol absorption. FM-VP4 is now under clinical investigation in phase II trials [33].

The discovery of ezetimibe introduced a novel and very selective principle of cholesterol absorption inhibition, which opens a new door to the treatment of hypercholesterolemia. There are numerous other cholesterol absorption inhibitory drugs in development or even under clinical investigation, which will be highlighted in Section 7.

## 4 DISCOVERY AND DEVELOPMENT OF EZETIMIBE

The discovery program that finally led to ezetimibe was started in the early 1990s at the Schering-Plough laboratories and initially aimed at the identification and development of an ACAT inhibitor [36, 37]. The rationale for this was due to the fact that ACAT is apparently involved in cholesterol trafficking in rodents [38]. In cholesterol-fed hamsters, the investigated predecessors of ezetimibe were capable to reduce the dramatically increased levels of hepatic cholesterol ester, whereas the reduction of serum cholesterol was only less pronounced (e.g., 0–10%) [39, 40]. Furthermore, these studies assessed a considerable divergence between the in vivo activity and the in vitro inhibition of ACAT. Despite the lack of knowledge of the distinct molecular target, a broad chemical program was initiated that generated several ß-lactam scaffold structures [41]. However, none of the gained compounds was a potent ACAT inhibitor but paradoxically showed in vivo activities, including a modest to strong lowering effect on serum cholesterol in the cholesterol-fed hamster model (10–43%) [36]. These experiments led to the conclusion that the tested compounds inhibit cholesterol absorption via a novel mechanism of action, which is apart of ACAT. Already at this point, various data according to structure–activity relationship (SAR) were available but the target protein was still unknown. A comprehensive discussion of the related SAR is beyond the scope of this contribution but given elsewhere by excellent reviews [37, 42]. In consequence that there was no suitable in vitro assay available, and the ongoing research program was strictly dependent on in vivo experiments in appropriate animal models. It is worth noting that such an in vivo optimization process is a very challenging medicinal chemistry approach since the intrinsic activity of a compound is indistinguishable from differences in bioavailability and metabolism. Nevertheless, in 1994 this effort culminated in the discovery of the 2-azetidinone SCH48461, which was reported to be the most effective compound in vivo and reduced serum cholesterol in hamsters, rats, and rhesus monkeys at considerable low effective dose ($ED_{50}$) values of 1, 2, and 0.2 mg/kg per day, respectively [36, 43]. In the same study it was assessed that SCH48461 inhibited the accumulation of cholesterol and cholesterol esters in the serum of cholesterol-fed hamsters, whereas the specific ACAT inhibitor CI-976 only minimized serum cholesterol esters but had no effect on serum cholesterol levels. Thus, it was again suggested that cholesterol lowering by ezetimibe-related compounds such as SCH48461 represents a novel and so far undiscovered mechanism that is located upstream from ACAT within the cholesterol uptake machinery.

It was found that SCH48461 is subjected to extensive metabolism including oxidation and glucuronidation, making it difficult to identify exactly the active species. To address this issue, Van Heek et al. performed animal experiments using bile-duct-cannulated rats. In this study, the cholesterol-lowering activity of SCH48461 itself was compared with its metabolites containing bile, which was collected via a bile duct cannula from animals after previous SCH48461 administration (Fig. 2) [44]. Interestingly, SCH48461 was capable of inhibiting intestinal $^{14}$C-cholesterol absorption by 70%, whereas the "metabolite bile" inhibited the absorption by greater than 95%. These data implied that metabolite formation plays an important role in drug activity. The major metabolite and concurrently the most active moiety in bile was identified as the C4-phenolic glucuronide of the demethylated parent compound (SCH53695). Consistently, the in vivo activity of the accordant biliary metabolite fraction was identical to that of authentic SCH53695. The predominating metabolite remained mainly in the intestinal lumen when delivered intraduodenally, that is, the glucuronide is not absorbable from the upper small intestine. This led to the premature assumption by the authors that the glucuronide is the active moiety, which was refuted later. Altogether, this in vivo metabolism-based approach led to the conclusion that drug glucuronidation facilitates extensive drug recycling to the side of action via an enterohepatic circulation. In addition, it was clarified that dealkylation of the parent structure SCH48461 increases the cholesterol-lowering activity that directed research again to a substantial chemistry synthesis program, which finally yielded a potent second-generation cholesterol absorption inhibitor, SCH58235, later known as ezetimibe (Fig. 3) [45]. Thus, ezetimibe represents a premetabolized and optimized structure of SCH48461 that showed a 50 and

**Figure 2** Schematic overview of the performed in vivo metabolism-based approach for the discovery of more potent cholesterol absorption inhibitors [54]. Within the first part of the study, blank bile or "metabolite" bile, which was generated after oral administration of SCH48461, was collected via a bile duct cannula. In the second part, "metabolite" bile or blank bile mixed with original SCH48461 was given intraduodenally to bile-duct-cannulated and intact rats. The inhibitory effect on intestinal cholesterol absorption was observed by determination of $^{14}$C-cholesterol levels in liver and plasma. more than 400 times increased cholesterol-lowering activity in hamsters and rhesus monkey, respectively [44, 45]. Subsequently, ezetimibe proved its markedly cholesterol and LDL-lowering effect in various animal species such as mice, rats, hamsters, dogs, and rhesus monkeys with substantially increased activity compared to its predecessor (Fig. 4). Later on, numerous clinical trials proved the efficacy and safety of ezetimibe in LDL-C-lowering therapy in hypercholesterolemic patients.

In conclusion, the ezetimibe-associated research program enabled deeper insights into the physiological mechanisms of intestinal sterol absorption. The discovery of ezetimibe was an elegant exception of today's typical rational drug design, which is characterized by novel target-related technologies such as genomics, proteomics, high-throughput screening, and molecular structure modeling [46]. Thus, it is expected to promote a more directed approach toward drug discovery but requires detailed knowledge about the respective molecular target. On the contrary, it is often reported that rational drug design sometimes leads down a blind alley, that is, compounds with insufficient in vivo effects or with unacceptable pharmacokinetic properties are yielded. Referring to ezetimibe, neither the molecular receptor nor the explicit mechanisms of intestinal cho-

lesterol absorption were known. In accordance with this, none of the "modern" tools of drug discovery played a significant role in the development of this novel lipid-lowering agent. Nonetheless, the tremendous effort of creative animal experiments and SAR-based in vivo and chemical optimization enabled the establishment of this new and promising drug principle. Thus, one could learn from the ezetimibe story that the development of a successful pharmaceutical drug does not necessarily require accurate understanding of the molecular target but needs creative solutions and "old-fashioned" experimental know-how.

## 5 EZETIMIBE—A PORTRAIT

### 5.1 Physicochemical Properties

From the chemical point of view, ezetimibe (IUPAC name:1-(4-fluorophenyl)-3(*R*)-[3-(4-fluorophenyl)-3(*S*)-hydroxypropyl]-4(*S*)-(4-hydroxyphenyl)-2-azetidinone; empirical formula: $C_{24}H_{21}F_2NO_3$; molecular weight: 409.43 g/mol) belongs to the class of 2-acetidinones, which are characterized by a ß-lactam scaffold structure (Fig. 4). Thus, in comparison to several penicillins, ezetimibe appears to be unstable at alkaline pH values as caused by cleavage of the ß-lactam ring [47]. It is a white, crystalline powder that is freely soluble in methanol, ethanol, acetonitrile, and acetone but practically insoluble in water (0.007 g/L, pH 2–9). The drug is stable at ambient temperature and melts at about 163–166°C [48]. Because of its distinctive lipophilicity (calculated log P = 3.49) a bioconcentration factor (ratio of the substance concentration within a cell compared to the concentration of the surrounding water) was estimated to be above 250 at pH 2–8. Hence, it is suggested that ezetimibe may be easily absorbed from the intestinal lumen into the enterocytes. On the other side, its lack of water solubility counteracts this theoretical prediction of drug uptake whereby ezetimibe belongs to the class II compounds of the biopharmaceutical classification system (low solubility, high permeability) [49]. Due to its free phenolic OH group, ezetimibe is only a very weak acid ($pK_a = 9.72$), which means that under physiological conditions (pH 7.4) the drug is predominately present in its molecular form (99.5%), whereas in the gut (pH 8–9), it undergoes increasing ionization along the intestine (2–16%). The latter may limit passive drug absorption of ezetimibe.

### 5.2 Pharmacodynamics

As introduced above, ezetimibe represents the first compound of a new class of lipid-lowering drugs that selectively inhibits the intestinal absorption of biliary and dietary cholesterol without influencing the absorption of other dietary lipids such as triglycerides, fat-soluble vitamins, or bile acids [50]. Animal experiments conducted in rodents clearly verified that the mechanism of ezetimibe is not explained by inhibition of pancreatic lipases, bile acid sequesting, and without influence on the intestinal sterol-efflux pumps ABCG5/G8 and the acute hepatic or intestinal cholesterol synthesis [51–53]. Using radiolabeled molecules, it has been demonstrated that ezetimibe acts at the luminal membrane of the enterocytes along the small intestine [54]. The exact mode of its pharmacodynamic action was recently elucidated as inhibition of the putative sterol-transporting protein NPC1L1. NPC1L1 features nearly 50% amino acid homology to NPC, a protein that functions in intracellular cholesterol trafficking and that is defective in the hereditary cholesterol storage disease Niemann–Pick type C. The origin of the hypothesis that NPC1L1 may be involved in the intestinal cholesterol absorption came from a genomic-bioinformatics approach. In brief, human and rodent complementary deoxyribonucleic acid (cDNA) libraries were screened for anticipated target characteristics of a potential sterol transporter as transmembrane domains, extracellular signal sequences, and cholesterol sensing motifs that identified the credible candidate NPC1L1 [26]. As expected, the small intestine, as the known site of cholesterol absorption, showed the highest expression levels of NPC1L1. Thereafter, it was convincingly demonstrated by an animal study using NPC1L1-deficient mice that this protein may be the target of ezetimibe and the major determinant of intestinal cholesterol absorption. In the absence of NPC1L1, the mice exhibit a substantial reduction in absorbed cholesterol (70%), which was similar to the effects observed in ezetimibe-treated wild-type animals (68–73%) and intractable to further reduction by additional ezetimibe administration (Fig. 5) [26]. Together, these observations led to the suggestion that NPC1L1 is essential for the intestinal sterol uptake and may be the molecular target of ezetimibe. However, this study failed to demonstrate the direct binding of ezetimibe to NPC1L1 in overexpressing non-enterocyte cells.

Preclinical animal studies showed that ezetimibe effectively inhibited intestinal cholesterol absorption and reduced both plasma cholesterol and LDL-C in a dose-dependent manner in rhesus monkeys ($ED_{50} = 0.0005$ mg/kg day), dogs ($ED_{50} = 0.007$ mg/kg day), rats ($ED_{50} = 0.03$ mg/kg day), hamsters ($ED_{50} = 0.04$ mg/kg day), and mice ($ED_{50} = 0.7$ mg/kg day) [55]. In chow-fed dogs it was assessed that comedication of ezetimibe with HMG-CoA reductase inhibitors resulted in a synergistic and markedly increased serum cholesterol reduction compared to monotherapy

**Figure 5** Cholesterol absorption in homozygous (–/–) and heterozygous (–/+) NPC1L1 knockout mice as well as wild-type animals (+/+) with or without ezetimibe treatment (EZE, 10 mg/kg). Mice were fed a standard chow (A and B) or a diet containing 0.1% sodium cholate (C and D) and orally gavaged with $^{14}$C-cholesterol. Acute cholesterol uptake (2 h) was studied in (–/–) and (+/+) mice (E and F). Asterisks indicate significance levels [*$p < 0.001$ for comparison with (+/+) and (+/–) mice; **$p < 0.001$ and ***$p < 0.05$ for comparison with (+/+) only]. (Reproduced from [26], with kindly permission of the publisher.)

with either agent. Dose-finding studies including several hundred patients revealed a daily dose of 10 mg to be sufficient for maximal cholesterol-lowering effect [56]. In humans, this ezetimibe dose reduced cholesterol absorption by 54%, whereas its lowers LDL-C by about 15–20% [57–59]. On the other side, the increase of high-density lipoprotein cholesterol (HDL-C) was only low. Compared to statins, the LDL-C lowering effect is equivalent or even less pronounced [50]. Consequently, the relevance of ezetimibe monotherapy is limited (e.g., statin-intolerant patients). Furthermore, this is encouraged by the fact that ezetimibe treatment results in compensatory increase of endogenous cholesterol synthesis, which can be antagonized by the combination with statins [12, 60]. The combination therapy with statins leads to a dual and complementary cholesterol-lowering action since both major sources of body cholesterol are modulated (i.e., intestinal absorption and endogenous synthesis). Interestingly, statins were shown to increase the intestinal cholesterol uptake [32]. Therefore, both ezetimibe and statins break down each others compensatory mechanisms, which affect their therapeutic effects, that is, enhanced cholesterol synthesis by ezetimibe and the increase in cholesterol absorption caused by statins. Thus, the main indication for ezetimibe is a combination therapy with statins. Consequently, this combination provides an additional LDL-C reduction of 18–20%, which is distinctly above the effect that is generated by doubling the statin dose (~5%) [61–63]. For instance, when a combination of 10 mg ezetimibe with 80 mg simvastatin was used, the average LDL-C reduction was 60%, which is greater than can be attained

**TABLE 1 Effects of Ezetimibe and Statins on Serum Levels of Total Cholesterol, LDL-Cholesterol (LDL-C), Triglycerides (TG), and HDL-Cholesterol (HDL-C) in Patients with Primary Hypercholesterolemia[a]**

[a]Values are given in mean % change from baseline [73].

with any statin alone (Table 1) [64]. Given this, the pharmacological effects of statins are markedly bolstered by ezetimibe, which requires only lower doses of statins and may lead to a smaller incidence of side effects. In experimental animal models ezetimibe profoundly minimized diet-induced atherosclerosis [65]. A similar outcome benefit is expected in humans as impressively shown for statins [8–10]. Until now, a confusing multiplicity of clinical trials employing ezetimibe and statins were published. However, outcome studies that investigate ezetimibe with or without statins are not available or still in progress, and no results are anticipated for several years [66].

Beyond the well-documented efficacy of ezetimibe in LDL-C lowering, also the enteral absorption of the phytosterols campesterol and sitosterol, molecules that are highly structurally related to cholesterol, is effectively reduced by ezetimibe [67]. In patients with sitosterolemia, a rare, autosomal recessively inherited sterol storage disease characterized by excessive absorption of these plant sterols, ezetimibe decreased the serum concentrations of sitosterol and campesterol by 21 and 24%, respectively [68]. Thus, ezetimibe offers a valuable therapeutic option for this potential life-threatening disease. Since these plant sterols are not endogenously synthesized as is the case for cholesterol, their reduction by ezetimibe demonstrates a direct drug effect that can be used as a surrogate for ezetimibe efficacy.

An open question associated with the pharmacodynamics of ezetimibe is whether the parent compound or its glucuronide represents the active moiety and whether the pharmacologic binding site of the postulated molecular target (NPC1L1) is located within the enterocytes or at the apical (luminal) membrane.

With regard to the latter question, Davies et al. detected that the NPC1L1 protein is expressed intracellulary in transfected HepG2 cells [69]. Contradictory to this, in vitro studies by the manufacturer described an apical target localization to emphasize the nonsystemic mode of ezetimibe action [70, 71]. Finally, Yu et al. clarified these diverging findings [72]. They found that NPC1L1 undergoes subcellular translocation in depending on the cellular content of cholesterol, that is, dietary cholesterol excess leads to intracellular existence of NPC1L1, which is the case in a high-fat western diet. From the current point of view only unchanged ezetimibe appears to be the active principle, which is discussed in detail in Section 5.3.

Ezetimibe was shown to be well tolerated in monotherapy and in combination with statins in thousands of patients [73]. Adverse drug effects were reported in ≥2% of patients and thus at a greater incidence compared to placebo including fatigue, abdominal pain, diarrhea, infections, and muscle pain. Additionally, very recent postmarketing studies assessed

that for ezetimibe when coadministered with statins, the incidence of significantly elevated liver transaminases was more markedly increased than in patients treated with HMG-CoA inhibitors alone (1.3 vs. 0.4%). Also very rare cases of myopathy and rhabdomyolysis, even during ezetimibe monotherapy, were described [74, 75].

After all, ezetimibe inhibits intestinal cholesterol and plant sterol absorption, which leads to clinically relevant reduction of serum LDL-C and plant sterols and offers a novel therapeutic approach for patients with hyercholesterolemia or sitosterolemia. The mainly well-tolerated combination of ezetimibe with statins inhibits the compensatory increase in cholesterol synthesis and leads to additional reduction in serum cholesterol levels.

### 5.3 Pharmacokinetics

After oral administration, ezetimibe is rapidly absorbed into the enterocytes after liberation from its immediate release dosage form (Zetia, Ezetrol) along the upper intestine, that is, the site of highest NPC1L1 expression and cholesterol absorption. Even a few minutes after intraduodenal delivery, the drug was detected in portal blood flow of rats [54]. Despite its high lipophilicity and its nearly water insolubility, it is expected that ezetimibe is rather poorly absorbed from the gastrointestinal tract. Accordingly, the absolute oral bioavailability has not been determined due to the absence of a parenteral application form. Furthermore, for the systemic ezetimibe exposure, no dose proportionality was assessed, which implies an involvement of active carriers that may limit intestinal drug absorption [76]. With regard to this, ezetimibe was identified as an in vivo and in vitro substrate of the multidrug transporting efflux pump P-glycoprotein (P-gp) [77]. However, once in the enterocytes, ezetimibe undergoes nearly complete intestinal glucuronidation to its major phenolic glucuronide (SCH60663), which accounts for approximately 90% of the systemic drug exposure (Fig. 6) [54, 78]. Additionally, traces of a benzylic glucuronide (SCH488128) were assessed. Later on, the uridine diphosphate (UDP)-glucuronosyltransferases (UGTs) 1A1, 1A3, and 2B15 were demonstrated to be the relevant isoenzymes for human metabolism [79]. The parent compound and its conjugated metabolite were shown to be subjected to hepatic uptake from the portal blood and subsequent biliary secretion [54]. The multidrug resistance-associated protein (MRP) 2, an ATP-consuming efflux transporter expressed in liver, kidney, and intestine, was identified as the major determinant for intestinal and heptobiliary secretion of the glucuronide [80]. Consequently, Mrp2 deficiency in rats led to diminished glucuronide elimination via feces but dramatically increased serum levels of the respective phase II metabolite. Altogether this creates an enterohepatic recirculation that enables repeated delivery of ezetimibe predominately in its glucuronized form back to the

**Figure 6** Biotransformation pattern of ezetimibe in humans (CYP, cytochrome P450 enzyme; UGT, UDP- glucuronosyltransferase).

site of action an in turn results in a long-lasting sterol-lowering effect and a high terminal half-life of about 20–24 h [76, 78]. Thus, it is sufficient to dose the agent once daily. Using a mathematical approach based on a population of a pharmacokinetic model, Ezzet et al. showed that the recycled amount of ezetimibe accounts for nearly 15–20% of the administered dose [81]. Nevertheless, the glucuronide fraction, which is secreted into the intestinal lumen, is not directly capable to inhibit the NPC1L1 protein because it is not absorbable from the upper parts of the gut due to its hydrophilicity (log $P = 1.18$) and ionic character ($pK_a = 2.78 \rightarrow$ pH 8–9, >99.9%) as well as the intracellular localization of the NPC1L1 protein [69]. This theoretical assumption was supported by an animal study [54]. In the lower intestine (i.e., terminal ileum and colon), the metabolite is degraded by cleavage enzymes from the bacterial flora to the parent compound. Thus, unchanged ezetimibe is now available for reabsorption from the proximal colon but not for immediate cholesterol absorption inhibition because this site of drug release is not the site of intestinal cholesterol absorption. Consequently, the expression level of NPC1L1 is only marginal in this intestinal segment [26, 69]. Therefore, the systemic drug concentration, which continuously provides ezetimibe to the enterocytes via the venous blood and not exclusively the intestinal drug amounts, dictate the drug efficacy of ezetimibe [56]. The latter seems only relevant during the initial period drug absorption, whereas unexceptional free ezetimibe from the digested tablet is on hand and invariably responsible for NPC1L1 modulation from the luminal site of the gut.

The nonsecreted portion of the drug appears via the portal vein after passing through the liver in the central compartment, which produces a first serum maximum within one hour. In the blood, ezetimibe and the glucuronide are highly bound to plasma proteins (>90%). The serum concentration–time profiles of ezetimibe ($C_{max} = 3$–$10$ ng/mL) and its glucuronide ($C_{max} = 45$–$75$ ng/mL) are characterized by multiple peaks that reliably appear at the time of food ingestion (Fig. 7). This is most likely caused by food-triggered emptying of the gall bladder and boluslike translocation of glucuronide containing chyme to the hydrolytic environment of the colon by the meal-induced gastroileocecal reflex [77, 82]. Thus, cumulative amounts of repetitively released ezetimibe are reabsorbed from the colon, which is enforced by the low expression levels of P-gp, MRP2, and the UGTs in this region of the bowel. Thereby, the second and third serum peaks of unchanged ezetimibe are even higher than the initial one (Fig. 7).

In general, the pharmacokinetics of ezetimibe is characterized by a high intersubject variability [35–60% for the area under the curve (AUC) values] the reasons of which are so far unknown. In a study of eight healthy subjects using radiolabeled $^{14}$C-ezetimibe the fecal and renal elimination 240 h after drug administration was approximately 78 and 11% of the administered 20-mg dose, respectively [78]. In urine, predominately the glucuronide (95%) is excreted, whereas in stool it is the unchanged ezetimibe (85%) as caused by bacterial hydrolysis [77, 83]. Hence, a substantial part of the dose (~10%) undergoes unknown metabolism and elimination pathways or remains in the body.

In contrast to statins, ezetimibe is only negligibly metabolized by CYP enzymes, which accounts for turnover of below 5% of the applied dose leading to a ketone structure (Fig. 6). In accordance with this, drug

**Figure 7** Serum concentration–time profiles of ezetimibe (left) and its glucuronide (right) after a single oral dose of 20 mg in eight healthy subjects. Arrows indicate time of food ingestion [83].

interaction studies with several well-established CYP substrates including caffeine (CYP1A2), tolbutamide (CYP2C8), warfarin (CYP2C9), dextromethorphan (CYP2D6), midazolam (CYP3A4), and cimetidin (CYP inhibitor) revealed no influence on the pharmacokinetics of each comedicated drug [76, 84]. This lack of oxidative metabolism by the CYP pathway suggested safety when combined with other agents such as statins that undergo mostly intensive CYP-mediated biotransformation. On the other side, unclear pharmacokinetic drug interactions with cyclosporine, gemfibrozil, and fenofibrate were described that led in part to several-fold increased serum concentrations of ezetimibe [76]. Very recently, inhibition of the efflux transporters P-gp and MRP2 by the mentioned interaction partners was elucidated as the molecular mechanism for these drug interactions. In accordance with this, transporter modulation caused markedly increased ezetimibe bioavailability, whereas induction of P-gp and MRP2 led to dramatically minimized serum levels of ezetimibe and in parallel to significantly reduced sterol-lowering effects [77, 83]. Hence, one could hypothesize that upregulation of these active elimination carriers by other known inducers such as St. John's wort, carbamazepine, or dexamethasone may deplete ezetimibe serum levels and its inhibitory effects on the intestinal sterol uptake. On the contrary, inhibition of P-gp and MRP2 by well-established substrates and/or modulating drugs such as statins, human immunodeficiency virus (HIV) protease inhibitors, verapamil, or ciclosporine most likely augment the systemic drug concentrations but may shorten the mean residence time of the drug. Accordingly, the combination of ezetimibe with simvastatin, lovastatin, and rosuvastatin caused elevated serum concentrations of ezetimibe and the respective statin by about 10–20% [85–87].

However, the clinical importance of both scenarios needs further clinical investigation. Nevertheless it cannot be excluded that enhanced serum concentrations due to pharmacokinetic drug–drug interactions may increase the risk for the described myotoxicity. Furthermore, nothing is known about the in vivo meaning of modulated ezetimibe glucuronidation which was shown in vitro by diclofenac and flunitrazepam [79].

Finally, ezetimibe possesses unique pharmacokinetic characteristics including extensive glucuronidation but practically no CYP-mediated biotransformation, which minimize its potential for drug–drug interactions with CYP substrates. However, the significant involvement of the efflux pumps P-gp and MRP2 in ezetimibe disposition is responsible for other pharmacokinetic interactions the impact of which needs further clarification.

## 6 NPC1L1—THE REAL TARGET OF EZETIMIBE?

The identification of the molecular basis of the ezetimibe effects has been an area of intensive research since its discovery in the 1990s. Modulation of pancreatic enzymes and inhibition of the hitherto described candidate proteins SR-BI, ABCA1, and ABCG5/G8 were excluded as potential mode of ezetimibe action [51, 53, 88].

The already mentioned report by Altmann et al. demonstrated very cogently that NPC1L1 might be the molecular target of ezetimibe and in turn that this protein may be the key player for intestinal cholesterol absorption [26]. In contrast to this study, during the ongoing research work, it was successfully shown that ezetimibe directly binds to HEK cells expressing NPC1L1 [70]. This is supported by a very recent paper from the Schering-Plough laboratories that detected a good correlation between the assessed in vitro binding affinity and the known in vivo potency of ezetimibe in different animal species. In addition, even SAR considerations could be addressed in this study [89].

In humans, functional relevant polymorphisms in the *NPC1L1* gene were described that were shown to affect the cholesterol-lowering potency of ezetimibe and thus underline that sterol lowering of ezetimibe seems to be exclusively realized by modulation of this putative sterol uptake carrier [90]. Also functional in vitro assays, which studied the cellular cholesterol and sitosterol uptake into Caco-2 cells in dependence on NPC1L1 expression and ezetimibe-mediated inhibition, clearly highlighted NPC1L1 as the molecular target of ezetimibe [91]. A further strong argument for this target represents an impressive study by Davis et al. that could show that deficiency of NPC1L1 in apoE null mice prevents atherosclerosis [92]. This was shown in the same manner for the treatment with ezetimibe [65].

Finally, the coordinate transcriptional regulation of NPC1L1 within the whole-body cholesterol homeostasis indicates an outstanding role of the NPC1L1 protein for cholesterol absorption. Referring to this, cholesterol and other ligands of the "lipid sensors" LXR and peroxisome proliferators-activated receptor (PPAR) δ were shown to suppress NPC1L1 expression, which limits excessive cholesterol uptake from the intestine [67, 93, 94]. Interestingly, it was also reported that ezetimibe itself is capable to downregulate NPC1L1 [95]. On the other side, inhibition of endogenous cholesterol synthesis by HMG-CoA inhibitors leads to an increased intracellular need of cholesterol that consequently results in a compensatory enhanced expression of NPC1L1 and subsequent higher intestinal cholesterol absorption [31, 32]. Given the high degree of homology

of NPC1L1 and other sterol-sensing domain-containing proteins (e.g., HMG-CoA reductase, ABCG5/G8), the emerging role of these proteins in cellular sterol trafficking is suggested. However, the distinct molecular regulation by nuclear receptors controlling NPC1L1 expression remains elusive.

Despite these investigations, some other possible target proteins and molecular mechanisms have been described for ezetimibe. In parallel to the discovery of NPC1L1 as the potential ezetimibe target, it was speculated that annexin-2 and caveolin-1, both cytoskeletal proteins, might be involved in concert in cholesterol absorption. In vitro, ezetimibe was capable to prevent the formation of the heterocomplex of both proteins, which was assumed to mediate the intracellular cholesterol transport [96]. Nevertheless, caveolin-1 knockout mice have a normal percentage of cholesterol absorption that disqualifies this protein complex to be of major relevance for the ezetimibe effects [97].

In another manufacturer-independent investigation study using membrane-impermeable photoreactive ezetimibe derivatives, it was demonstrated that ezetimibe binds to a 145-kDa integral membrane protein of the brush border membrane of small intestinal enterocytes identified as aminopeptidase N (CD13) [98]. However, this enzyme, which is normally involved in the endocytosis of viruses, showed no direct cholesterol absorption. Thus, it remains uncertain whether aminopeptidase N is an in vivo target of ezetimibe or is even involved in the cholesterol uptake cascade.

In addition, Seedorf et al. revealed that ezetimibe inhibits the in vitro uptake of oxidized LDL-C into human macrophages in a concentration-dependent manner, which could represent an interesting systemic mode of ezetimibe action that may prevent the formation of atherogenic foam cells [99].

In conclusion, there is ample evidence by numerous in vitro investigations, animal studies, and pharmacogenomic data from humans that NPC1L1 is indeed the molecular target of ezetimibe and the rate-limiting carrier for the intestinal absorption of cholesterol and plant sterols.

## 7 DRUGS OF THE FUTURE

Since it was demonstrated that inhibition of intestinal cholesterol absorption appears to be a promising pharmacological drug target to lower serum cholesterol, in parallel to the discovery of ezetimibe several other auspicious compounds affecting different steps within the intestinal cholesterol uptake cascade were developed. In accordance with the predominate use of ezetimibe in combination therapy, these compounds may be of interest as further options to achieve a higher degree of LDL-C lowering. This Section summarizes the recent proceedings in this area.

### 7.1 ACAT Inhibitors

As described in Section 2, the acyl CoA:cholesterol acyl transferase (ACAT) is a membrane-bound enzyme involved in intracellular esterification of cholesterol. ACAT is located in the rough endoplasmic reticulum of various tissues such as liver, intestine, macrophages, and blood vessels. Two isoforms, ACAT1 and ACAT2, were identified [100]. The latter is exclusively expressed in the liver and the intestine and might be of great significance for pharmacological intervention in order to block cholesterol uptake from the gut. Beside re-esterification of dietary cholesterol in the enterocytes, hepatic ACAT2 is involved in the secretion of very low density lipoprotein (VLDL) particles into the systemic circulation. Mice lacking ACAT2 showed nearly halved serum cholesterol levels compared to their wild-type counterparts [101]. Otherwise, ACAT1 in the vessel wall is responsible for macrophage-mediated storage of cholesterol esters. Thus, inhibition of ACAT was expected (1) to lower intestinal cholesterol absorption by limiting the assembly of chylomicrons, (2) to decrease the appearance of VLDL cholesterol in the blood, and (3) to diminish cholesterol accumulation into macrophages, which is critical for the development of plaque lesions. Numerous ACAT-inhibiting candidates, including DuP-128, F-1349, CL-277082, pactimibe (CS-505), and avasimibe (CI-1011), were evaluated. ACAT inhibitors were shown to decrease plasma cholesterol in various animal models [23, 102]. However, due to the low bioavailability of most ACAT inhibitors, these drugs seem only to interrupt the intestinal cholesterol absorption and in turn demonstrated only marginal effects on serum cholesterol in humans [33]. Furthermore, the unselective modulation of both isoenzymes by current ACAT inhibitors led to significant toxicological effects as emesis, changes in red blood cell morphology, and hepatic and adrenotoxicity. Substantial clinical data are only available for avasimibe and pactimibe. Both drugs are orally available but nonspecific inhibitors of ACAT. Avasimibe-treated minipigs exhibited a markedly increased fractional clearance rate of postprandial triglyceride-rich lipoproteins (VLDL), whereas an LDL-C-lowering effect was only observed at markedly higher doses. In humans, avasimibe reduced triglycerides by 16–23% but neither affected total cholesterol or LDL-C concentrations nor favorably altered coronary atherosclerosis [103, 104]. Similar results were

demonstrated for pactimibe by a very recent study including over 400 patients with coronary disease [105]. Taken together, current ACAT inhibitors failed to demonstrate substantial effects on LDL-C levels and atherosclerosis in humans. Despite the promising molecular target of ACAT and the fact that selective ACAT2 inhibitors may feature improved pharmacologic characteristics, one might raise the question if this class of drugs could even generate clinically significant effects.

### 7.2 MTP Inhibitors

The microsomal triglyceride transfer protein (MTP) is a heterodimer protein that catalyzes the transfer of triglycerides, cholesterol esters, and apolipoproteins across membranes and is therefore critical for the assembly of chylomicrons in the enterocytes and of VLDL particles in the liver. The exact molecular mechanism of lipid binding and transport by MTP remains so far uncertain. Abetalipoproteinemia is a rare inherited disease caused by genetic defects of this protein and characterized by hypocholesterolemia, malabsorption of fat-soluble vitamins, and the absence of apoB-containing lipoprotein particles. The inhibition of MTP is expected to reduce intestinal cholesterol absorption by modulating chylomicron secretion into lymph and to decrease hepatic VLDL secretion leading to decreased plasma levels of VLDL-C, LDL-C, and triglycerides. Several experimental MTP inhibitors such as BMS-201038 (lomitapide), BMS-212122, BMS-200150, JTT-130, CP-346086, and implitapide (BAY-139953) have been developed and investigated in vitro and in animal studies [23, 33, 106]. Nearly all of these compounds showed distinctive reduction of serum cholesterol and triglycerides in small animal models. However, only very little is known about the clinical effects of MTP inhibitors in humans. Implitapide, which was shown to prevent atherosclerosis in apoE knockout mice, was studied in 188 patients with primary hypercholesterolemia in a placebo-controlled, randomized, double-blind trial. It was shown that implitapide is capable to reduce LDL-C in a dose-dependent manner (8–55%) [23]. On the other side, this drug frequently caused adverse side effects as increased liver transaminases and gastrointestinal symptoms, especially at high doses, and consequently this compound is no longer in development. For CP-346086, an even more potent and orally active inhibitor of MTP, a substantial dose-dependent lowering of total serum cholesterol (47%), LDL-C (72%), and triglycerides (75%) with no influence on HDL was revealed in healthy human volunteers [107]. Treatment of patients with homozygous familial hypercholesterolemia with BMS-201038 (AEGR-733) led to a marked reduction of LDL-C and apoB-containing lipoproteins by up to 51 and 56% [106]. Under consideration of these observations, MTP-modulating drugs seem to be most suitable in patients with hepatic hypersecretion of apoB, including the metabolic syndrome or type II diabetes mellitus. Despite the impressive effects on serum lipids, the clinical impact of these drugs for the treatment of hypercholesterolemia remains still unclear. However, inhibition of MTP by different drugs was associated, as expected, with malabsorption of fat-soluble vitamins and hepatic steatosis, which is in line with reports of patients with ABL and MTP-deficient animals. The mentioned safety aspects have to be addressed in furture studies in order to exclude long-term toxicity (e.g., avitaminosis and hepatic and intestinal fat accumulation).

### 7.3 Bile Acid Reabsorption Inhibitors (BARI)

Due to the fact that bile acids represent a substantial part of the whole-body cholesterol pool, interruption of their intestinal reabsorption appears to be a promising pharmacological approach that is so far targeted by bile-acid-binding resins as noted before. Bile acids are actively taken up from the intestinal lumen of the ileum by the apical sodium-dependent bile salt transporter (ASBT [IBAT—ileal bile acid transporter]). Thus, specific inhibition of ASBT represents an alternative option to minimize bile acid reuptake. Interruption of this enterohepatic recirculation activates endogenous bile salt resynthesis in the liver by upregulation of cholesterol 7α-hydroxylase (CYP7A1), which mediates the rate-limiting turnover of systemic cholesterol to bile salts. Consequently, LDL receptors at the hepatocyte cell surface are upregulated to increase lipoprotein catabolism, and, subsequently, the serum cholesterol concentrations decrease. In addition, hepatic VLDL secretion is reduced, whereas the HMG-CoA reductase-catalyzed cholesterol synthesis is increased. As described for the other novel classes of cholesterol absorption inhibitors, also for BARI such as SC-435, S-8921, 264-W94, TA-7552, and HMR-1453, an explicit cholesterol-lowering effect was demonstrated in small animals [33, 108]. As expected, animal treatment with BARI was associated with increased fecal bile acid excretion and concomitantly enhanced hepatic activity of CYP7A but a decrease of serum LDL and total cholesterol levels. Moreover, combination of BARI with HMG-CoA reductase inhibitors elevated the LDL-C-lowering effects due to complementary modes of action. However, until now no clinical data are available for the use of BARI in humans. It was hypothesized that the nearly doubled fecal loss of bile acids, which was assessed in animal studies, may cause gastrointestinal side effects. Most likely this could be antagonized with low dose of bile-acid-binding resins.

### 7.4 Other NPC1L1 Inhibitors

During the development of ezetimibe, several structurally related compounds were discovered [37, 109]. Using in vitro binding experiments in NPC1L1-expressing cells and animal studies, some of these candidates showed an even higher potency than the parent compound [37, 89, 110]. It is worth noting that the detected in vitro binding affinity of these compounds represents no direct surrogate for their expected in vivo efficacy because the established NPC1L1 overexpressing cell lines differ markedly from the situation in human enterocytes (e.g., apical localization NPC1L1). Furthermore, using such in vitro assays, the pharmacokinetic fate of each compound is not considered but of immense impact on *in vivo* efficacy as discussed for ezetimibe. Nevertheless, it is expected that Schering-Plough and other companies will follow the proven strategy of NPC1L1 inhibition and design more potent cholesterol absorption inhibitors. Ultimately, the future work in this area will dictate how ezetimibe therapy is accepted into clinical practice and if ezetimibe in mono- or combination therapy will yield clinically significant outcome benefits.

## 8 CONCLUSIONS

Ezetimibe is the first compound of lipid-lowering drugs that selectively inhibits the intestinal cholesterol absorption. Modulation of the sterol uptake carrier NPC1L1 appears to be the molecular mode of ezetimibe action. The associated research project has revolutionized our current understanding of intestinal cholesterol trafficking. The drug was marketed without any knowledge of its distinct molecular target. Accordingly, the discovery of ezetimibe was an explicit exception to today's drug design. Nevertheless, despite the fact that no in vitro assay was available, by using very sophisticated animal studies and broad chemical synthesis programs the optimal structure of ezetimibe was acquired. In clinical trials, ezetimibe was shown to reduce serum LDL-C by about 20%. In combination with statins an additional cholesterol-lowering effect of 15–20% was generated. Ezetimibe possesses unique pharmacokinetic properties, including comprehensive glucuronidation, efflux transport by P-gp and MRP2, and enterohepatic recirculation but no CYP-mediated metabolism. Thus, ezetimibe exhibits a long terminal half-life of nearly 24 h, which enables a once-daily dosing regimen. Despite several pharmacokinetic drug–drug interactions reported, ezetimibe appears to be a safe and well-tolerated drug. Although ezetimibe markedly lowers intestinal cholesterol absorption and serum LDL-C in hypercholesterolemic patients, especially in combination with statins, significant clinical benefits in the form of a reduced morbidity and mortality must be proven. The promising strategy of cholesterol absorption inhibition is focused on numerous new classes of compounds that are under intensive investigation but still far from being introduced to the market.

# CARDIOLOGY—IN-DEPTH LOOK: KINASES AS THERAPEUTIC TARGETS IN THE HEART

Karin Mauer and J. Emilio Exaire
*Department of Medicine, Cardiovascular Section, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma*

## 1 KINASES AS PHARMACOLOGICAL TARGETS IN THE HEART—A NEW ERA IN MOLECULAR CARDIOVASCULAR THERAPEUTICS

Cardiovascular disease is the leading cause of morbidity and mortality in modern society, resulting in enormous health care costs. The spectrum of diseases encompasses a group of clinically heterogeneous ailments of the heart (e.g., ischemic heart disease or coronary artery disease, congestive heart failure, and cardiomyopathy) and of blood vessels (e.g., hypertension and atherosclerosis) with multifactorial origin, strongly influenced by race, gender, and environmental aspects. In recent years there has been extensive progress toward understanding the pathophysiology of cardiovascular disease, which has shown multiple cell signaling cascades. Anomalous activation of diverse neurohormonal systems (e.g., catecholamines, angiotensin II, endothelin-1, natriuretic peptides, cytokines, and growth factors), which are crucial for homeostasis under physiological conditions, play a role in the establishment and progression of cardiovascular disease. Furthermore, there is evidence that specific signaling pathways are involved in acute and chronic cardiovascular disease, and the molecules comprising these pathways are targets for future development of therapies. In fact, the efficacy of drugs such as angiotensin II and adrenergic receptor blockers provides confirmation that targeting these signaling pathways is valuable for the treatment of cardiovascular disease. Most of the signaling pathways consist of a cascade of protein kinases that transduce signals from a receptor on the cell membrane to the nucleus of the cell. This series of protein phosphorylation leads to specific cellular responses (e.g., gene expression, growth, and/or proliferation), and hypothetically it could be possible to modulate these events in order to achieve a desirable cellular effect. Since most of these signaling pathways and protein phosphorylation are mediated by these enzymes, changes in protein kinase activity by pharmacological agents could provide a therapeutic benefit in cardiovascular disease [1]. Even though there is an extensive selection of effective treatments that target cardiovascular disease (e.g., statins, β-blockers, antagonists of the renin–angiotensin system, calcium channel blockers, thrombolytic agents, and antiplatelet drugs), mortality associated to it remains high. Therefore, there is a need to develop new therapeutic agents that will positively impact quality of life and prolong survival.

Several protein kinases have been implicated in human cardiovascular disease by the successful use of G-protein-coupled receptor (GPCR) antagonists (e.g., protein kinase A and CaMKII mediate β-adrenergic receptor action) and in some cases by evidence of altered expression in diseased human heart tissue. In fact, the successful use of GPCR blockers have shown to reduce mortality from cardiovascular disease and suggests that a larger number of downstream kinases mediating the actions of these receptors are also

**TABLE 1 Protein Kinase Involvement in Heart Disease**[a]

| | | Experimental Models | |
|---|---|---|---|
| Kinase | Human Disease | Overexpression or Increased Activation | Knockout, Inhibition or Decreased Activation |
| AKT | Decreased activity (after LVAD) | Preserved function after I/R, but with increased MI size | Reduced recovery after ischemia (DN) |
| CaMKII | Increased expression (HF) | Hypertrophy, dysfunction, sudden death | Reduced remodeling and improved function after MI and isoproterenol |
| ERK | No change (HF secondary to ischemic disease) | Hypertrophy and increased contraction | NA |
| JAK | Decreased JAK2 activity (DCM)<br>Increased JAK1 activity (DCM) | Promotes cell survival<br>Prevents remodeling after MI | Reduced ischemic preconditioning |
| JNK | Increased activity (HF secondary to ischemic disease)<br>Decreased activity (after LVAD) | Atrial enlargement | Increased hypertrophy with pressure overload and aging (DN) |
| p 38 MAPK | Increased activity (HF secondary to ischemic disease)<br>Increased activity (after LVAD) | Fibrosis, dysfunction, and sudden death without hypertrophy | 1. Increased hypertrophy with pressure overload, Ang II, and isoproterenol<br>2. Hypertrophy without fibrosis with pressure overload<br>3. Reduced I/R-induced apoptosis and preserved cardiac function |
| PKA | Increased activity (HF) | Hypertrophy, dysfunction, sudden death | NA |
| PKC | Increased activity and expression (HF) | Improved function after ischemia (PKCβ) | Protection from ischemia (PKCε translocation) |
| PI3Kγ | | | 1. Impaired ADP-induced, but not collagen-induced platelet aggregation (protection against ADP-induced thromboembolic vascular occlusion)<br>2. Myocardial damage after chronic pressure overload<br>3. Reduced phosphorylation of NOS3, blunted NO production, and protection from PAF-induced negative inotropism<br>4. Improved contractile recovery after I/R<br>5. Attenuated hypertrophy and interstitial fibrosis in response to isoproterenol<br>6. Protection from isoproterenol-induced HF<br>7. Protection against Ang-II-mediated hypertensive response |
| AMPK | | Hypertrophy associated with glycogen accumulation and ventricular pre-excitation | 1. Insulin resistance, no overt cardiac phenotype (total α1 or 2-subunit KO)<br>2. Decreased glucose uptake, increased ATP depletion, and increased left ventricular dysfunction during ischemia (mutated α2 subunit)<br>3. Normal cardiac function during exercise, without ATP depletion (mutated α2 subunit)<br>4. No cardiac hypertrophy; during I/R decreased glucose uptake, glycolysis, and failure to increase fatty acid oxidation; impaired cardiac function and increased cardiac injury following reperfusion (mutated α2 subunit)<br>5. Cardiac hypertrophy associated with glycogen accumulation and ventricular pre-excitation |

**TABLE 1** ***Continued***

| Kinase | Human Disease | Experimental Models: Overexpression or Increased Activation | Experimental Models: Knockout, Inhibition or Decreased Activation |
|---|---|---|---|
| ROCK | | | 1. Normal basal and Ang-II-stimulated blood pressure, heart rate, and cardiac dimensions, but reduced perivascular fibrosis<br>2. Decreased perivascular and interstitial fibrosis after pressure overload<br>3. Reduced I/R injury, infarct size, myocardial fibrosis, and cardiac hypertrophy<br>4. Lower cardiac myocyte apoptosis and improved postischemic cardiac function |

[a]AKT, kinase originally encoded by akt murine thymoma viral oncogene; LVAD, left-ventricular assist device; I/R, ischemia/reperfusion; MI, myocardial infarction; DN, dominant negative mutant; CaMKII, multifunctional calcium/calmodulin-dependent protein kinase II; HF, heart failure; ERK, extracellular-signaling-related kinases; NA, not available; JAK, Janus kinases; DCM, dilated cardiomyopathy; JNK, jun N-terminal kinase; MAPK, mitogen-activated protein kinase; ang II, Angiotensin II; PKA, protein kinase A; PKC, protein kinase C; NOS, nitric-oxide synthase; NO, nitric oxide; PAF, platelet-activating factor; AMPK, AMP-activated protein kinase; KO, knockout.

potential therapeutic targets [2]. Most, if not all, intracellular signaling pathways depend on the phosphorylation status, and thus activity of involved proteins and all cellular functions (e.g., gene expression, cell adhesion, cell cycle progression, and differentiation) are modulated by the complex and specific interplay of kinases and phosphatases [3]. There are over 500 different protein kinases, and overall they facilitate the phosphorylation of diverse protein substrates within a given cell, which serves as a common form of signal

transduction. The kinase transfers a phosphate group from adenosine triphosphate (ATP) onto hydroxyl residues of serine or threonine (serine/threonine protein kinases), or of tyrosine (tyrosine protein kinases) on specific proteins, thereby modulating their function, which has an impact on different cellular processes. Protein kinase activity is regulated by phosphorylation itself or second messenger levels [e.g., cyclic adenosine monophosphate (cAMP) and calcium] controlled by GPCRs in response to extracellular signals [1, 2]. Protein kinases interrelate through a process known as cross talk, which reflects an interacting network rather than a sequential activation linked to one GPCR. Since GPCRs are positioned at the beginning of signaling pathways, activation of one receptor can modify multiple second messengers and mediators downstream of the cascade. Thus, antagonism at receptor level might not select between the beneficial and harmful effects of aberrant signaling in disease, and blocking the signaling cascade further downstream has more potential for greater selectivity [2]. Selective targeting of signaling pathways using protein kinase modulators could have a potential advantage over receptor blockers [4], and choosing the right biological target is one of the most critical decisions made in pharmaceutical research and development [5]. Recently, a lot of effort has focused on compounds that modulate different protein kinases in multiple settings. In fact, the cancer field has led the way in drug development directed both at normal and mutated protein kinases [4], and there is growing evidence showing that regulation of these enzymes has therapeutic interventional value in cardiovascular disease.

### 1.1 Key Events in the Development of Protein Kinase Inhibitors [6]

In the early 1980s the first protein kinase inhibitors were developed. Certain antagonists of the calcium-binding protein calmodulin (naphthalene sulfonamides) at higher concentrations were found to inhibit several protein kinases. In addition, when the naphthalene ring was replaced by isoquinoline, it was observed that the compound was no longer a calmodulin antagonist but retained the ability to inhibit protein kinases. Since these compounds were ATP competitive and cell permeable, a potential use in vivo was foreseen. Even though many of the compounds developed subsequently are of relatively low potency and selectivity, one of these compounds, fasudil hydrochloride (also known as HA1077 or AT877) progressed to human clinical trials in the early 1990s. This drug was approved in Japan in 1995 for the treatment of cerebral vasospasm after surgery for subarachnoid hemorrhage and associated cerebral ischemic symptoms.

The discovery that the antifungal agent staurosporine was an inhibitor of protein kinase C (PKC) at nanomolar concentrations led to the development of compounds such as Roche's Ro31-8220 and Goedke's Go6850 (also called GF109203X) used in cell-based assays. However, these and several other drugs were later shown to lack specificity. Nevertheless, several have progressed to human clinical trials, but it is unclear whether their efficacy results from the inhibition of PKC and/or other protein kinases. It has been shown that some of these also block cell-cycle progression by inhibiting the cell-cycle checkpoint-control kinase CHK1. In fact, the compound PKC412 by Novartis has been tested in human clinical trials for the treatment of advanced cancers. Furthermore, it also seems to inhibit retinal and choroidal neovascularization in murine models and is being evaluated in clinical trials for the treatment of ischemic retinopathy.

The compound LY333531 inhibits the PKC-β isoform more potently than other PKC isoforms and has been said to normalize PKC activity in the retina and kidneys of diabetic rats, and it has been tested in phase III clinical trials for the treatment of diabetic microvascular disease.

Interestingly, some of the initial drugs to be approved that inhibit a specific protein phosphatase or protein kinases were cyclosporin and rapamycin. However, the development of these compounds was achieved without knowing their exact mechanism of action and focusing only on their clinical efficacy. Most of the effort to develop agents that target specific protein kinases has been focused in the field of oncology. Actually, some of the most promising drugs being developed as anticancer drugs are tyrosine kinase inhibitors. Key studies carried out 10–15 years ago, which identified main compound classes of tyrosine kinase inhibitors, such as quinazolines and tyrphostins, have greatly influenced progress in this area. However, it was not until May 2001 that imatinib was approved for clinical use as a protein kinase inhibitor [6]. By the year 2002, at least 3 protein kinase inhibitors (fasudil, rapamycin, and Gleevec) and 1 phosphatase inhibitor (cyclosporin) had been approved for clinical use in specific pathologies, over 20 other protein kinase inhibitors were being tested in human clinical trials and many more were at the preclinical stage [6]. By the year 2007 at least 8 drugs that target kinases have received regulatory approval for specific oncologic conditions, and over 100 additional compounds that block protein kinase activity are being evaluated [1]. Consequently, protein kinases are the second largest group of pharmaceutical targets after GPCRs, comprising between 20 and 30% of the drug discovery programs. Since protein kinases encompass one of the largest enzyme families encoded by the

human genome, there are many potential targets for drug development. Much of the effort so far has been directed toward oncologic conditions in which protein kinase inhibitors are being well tolerated compared to conventional chemotherapeutic treatments. The safety profile seen so far in human clinical trials is encouraging since several of these protein kinase inhibitors are not very specific. In order to determine whether a drug is exerting its effect through blocking of a particular protein kinase, it needs to be evaluated when a drug-resistant mutant is overexpressed or replaces the wild-type enzyme, which has been shown in only a few cases (e.g., mutations in Abelson tyrosine kinase, or ABL, can make it resistant to Gleevec, which causes a relapse in patients who have an advanced stage of chronic myelogenous leukemia) [6] .

There is a need to use different ways to screen for and/or design inhibitors of particular protein kinases based on a detailed understanding of their catalytic and regulatory properties to fully understand the essential role in the pathogenesis of disease as well as for research purposes. In fact, specific protein kinase inhibitors that cannot be used as drugs because of toxicity, pharmacology, or solubility (e.g., PD98059 and SB203580) have helped broaden our understanding in specific therapeutic areas [6]. The majority of the kinase inhibitors currently in development are focused on diverse oncologic conditions, and kinase involvement in cancer seems to be different than in cardiovascular disease. In cancer cells, the aberrant behavior of kinases is associated with genetic or somatic mutations, while in cardiovascular disease this is because of enhanced stimulation by activated neurohormonal systems. The successful use of kinase inhibitors in cancer supports its application in the treatment of cardiovascular disease [1]. Currently, there are two kinase antagonists under development targeting the receptors either by antibodies or small molecule. Antibodies target receptor tyrosine kinases and behave similar to receptor blockers while small-molecule kinase inhibitors target signal transduction [1].

### 1.2 Mitogen-Activated Protein Kinases (MAPKs)

Small G-proteins are low-molecular-weight monomeric G-proteins (e.g., Ras, Rho, Ran, Rab, Arf, and Kir/Rem/Rad) that act as a molecular "switch" controlled by a guanosine diphosphate/triphosphate (GDP/GTP)-binding cycle, and regulate several intracellular signaling events, such as cell proliferation, apoptosis, migration, gene expression, cytoskeletal reorganization, intracellular vesicle trafficking, and microtubule organization during the cell cycle. These important cellular responses are mediated partly by their downstream effectors known as MAPKs [i.e., extracellular signal regulated kinase (ERK), c-Jun $NH_2$-terminal kinase (JNK), and p38 MAPK] [7]. There are several members in the MAPK family that can be classified into four groups: (1) the classical MAPKs (ERK1 and ERK2), (2) JNKs (JNK1, JNK2, and JNK3), (3) p38 MAPKs (p38α, p38β, p38γ, and p38δ), and (4) atypical MAPKs (ERK3, ERK5, and ERK8). Traditionally, JNKs and p38 MAPKs are considered as stress-activated MAPKs and have been implicated in cardiovascular disease. In animal models of cardiovascular disease, such as hypertension and atherosclerosis, MAPKs appear to be activated in vascular tissues by mechanical and oxidative stress, vasoconstrictors, and growth factors [7]. JNK1 and JNK2 are ubiquitously expressed and JNK3 appears to be neural specific. Some of JNK's substrates include transcription factors (e.g., AP-1, p53 and c-Myc), as well as nontranscription factors that are related to apoptotic cell death factors (e.g., Bcl-2 family members). In cultured vascular smooth muscle cells (VSMCs), JNKs are activated by environmental stress (e.g., oxidative stress and pro-inflammatory cytokines) and growth factors [7]. ERK1/2, JNK, and p38MAPK signaling cascades play an important role in multiple processes, including cell differentiation, proliferation, and death, as well as homeostasis and acute response to hormones. Despite being ubiquitous, their activation mechanism, substrate preference, and functions are often cell specific. ERK1/2 activation depends on growth stimuli (e.g., ET-1, phenylephrine, and Ang II in cardiac myocytes) and mediates growth and cytoprotective functions. In contrast, JNK and p38MAPK are activated by cellular stress (e.g., ischemia, pro-inflammatory cytokines, and hypertrophic stimuli). There is controversy whether activation plays a causal or consequential role in cardiac disease since conflicting results may be associated with the existence of multiple isoforms and nonselectivity of current inhibitors [1]. Selective oral inhibition of p38α isoform with SD-282 in animal models of myocardial injury improved cardiac function, stopped cardiac myocyte apoptosis, and decreased macrophage infiltration. In cultured rat cardiomyocytes exposed to hypoxia/reoxygenation, inhibition of p38α with SB203580 notably avoided induced cell death. Furthermore, estrogen has proven to decrease p38α activation and concomitantly favor p38β activity, which is barely affected by hypoxia/reoxygenation. This implies that estrogen differentially modulates the two major p38 isoforms and that cell death is mainly regulated by p38α. There is evidence that there are differences in myocardial responsiveness to ischemia/reperfusion (I/R) between the murine and the porcine models, since p38 activation in the mouse participates in acute cellular injury and death, while in the pig it seems not to have a contributing effect on these parameters. Thus, species specificity is important

to have in mind when using p38 as an aim for intervention [1].

MAPK p38 is a point of convergence for numerous signaling processes that have impact on different events that are essential in inflammation [8]. Over 100 p38 inhibitors have been reported, and most of them compete directly with ATP for binding to a kinase domain, which is structurally conserved in all catalytically active kinases to facilitate the transfer of the γ phosphate from ATP to the substrate. A few allosteric inhibitors do not fill the adenosine pocket, but their binding induces a conformational change that prevents the kinase from binding ATP. These blockers have varying degrees of selectivity, and the impact this might have on the safety profile of each compound after chronic treatment in humans needs to be better established [8].

### 1.3 G-Protein-Coupled Receptor Kinases (GRKs)

There are seven members in the GRK family that contribute to the regulation and signal transduction via GPCRs. GRK levels change in pathological settings such as heart failure, hypertrophy, and hypertension. GRK2 (or β-ARK1) modulates β-adrenergic receptors (β-ARs) in the heart, which are overexpressed in human heart failure. In fact, the attenuated contractile response to β-adrenergic stimulation in cardiac dysfunction has been linked to increased β-ARK1 expression and activity. Indeed, there is data to suggest that cardiac β-ARK1 expression and activity increases with disease severity. In addition, in patients with a left ventricular assist device restitution of β-AR signaling in the heart has been associated with decreased myocardial β-ARK1 activity. Pressure and volume overload appear to upregulate β1-ARs associated with subcellular redistribution of GRKs in the failing heart. In animal studies, β blockers have been described to reverse GRK-mediated desensitization and downregulation of cardiac β-ARs. Furthermore, β blockers seem to prevent increased β-ARK1 activity in the failing human heart [1]. Interestingly, exercise training in a model of spontaneous hypertension improves the inotropic and lusitropic response to β-AR stimulation, which seems to correlate with lower β-ARK1 and enhanced phosphorylation of calcium cycling proteins [1].

### 1.4 Phosphatidylinositol 3-Kinase (PI3K)

PI3Ks have central roles as lipid and protein kinases in several intracellular signaling events. In response to diverse biological stimuli, PI3Ks primarily phosphorylate phospholipids containing inositol, which have an important role as second messengers that work as a docking platform for lipid-binding domains of proteins triggering downstream kinase cascades [5]. Class IA members (i.e., PI3Kα, β, and δ) act in response to hormones, growth factors, cytokines, integrins, and other extracellular stimuli to regulate diverse processes, including cell metabolism, proliferation, growth, survival, and motility. The only member of class IB (i.e., PI3Kγ) is activated by GPCRs and Ras and has been shown to regulate MAPK cascades. There is the possibility that antagonism of such a central signaling molecule is likely to be accompanied by unwanted side effects [5]. While PI3Kα and PI3Kβ are expressed ubiquitously, PI3Kγ and PI3Kδ expression is mostly limited to the hematopoietic system, even though PI3Kγ can also be detected in the heart, endothelium, and brain. Thus, a PI3Kγ inhibitor will affect the signaling network of any given GPCR only when they are coexpressed and activated in the same cell type and tissue. Apparently, PI3Kγ shows preference to certain GPCRs and Gβγ-PI3Kγ interaction is only one event among many that is triggered by the dissociation of the trimeric G proteins subsequent to GPCR activation. Thus, even when PI3Kγ inhibition is complete, the signal coming from an activated GPCR is expected to be just reduced, rather than abolished. In that way, PI3Kγ antagonism constitutes a more subtle mode of intervention than the complete block of all downstream signals that is achieved by inhibitors that act directly on the GPCR [5]. The catalytic subunits of class IA isoforms (p110α, p110β, and p110δ) are activated by receptor tyrosine kinases, while the one in class IB members (p110γ) is activated by the βγ subunit of heterotrimeric G proteins. It has been described that PI3K has several biological roles associated with cancer, inflammation and autoimmunity, as well as cardiovascular functions. For example, the PI3K-Akt-GSK3β pathway increases cardiac protein synthesis and thus promotes hypertrophy [1].

### 1.5 Rho-dependent Serine–threonine Kinases

Rho is part of a family of small GTP-binding proteins that contribute to intracellular signal transduction, which regulates gene expression and cytoskeletal reorganization and which is triggered by activation of growth factor receptors and GPCRs. In resting cells, Rho is found primarily in the cytosol in its inactive GDP-bound form, and when certain agonists stimulate the cell, the Rho-GTP compound is translocated to the cell membrane, where it interacts with its specific targets. It has been shown that in the cardiovascular system, Rho modulates contraction of vascular smooth muscle by regulating calcium sensitivity. Rho kinase (ROCK), with its two highly homologous isoforms ROCK1 and ROCK2, is one of the downstream effectors of Rho [4, 9]. Even

though both isoforms are ubiquitously expressed, ROCK1 is mostly expressed in the kidney, lung, liver, spleen, and testis, whereas ROCK2 is preferentially present in the heart and the brain. ROCK substrates include different proteins such as myosin light-chain phosphatase, adducin, intermediate filaments (such as vimentin and desmin), the Na/H exchanger, the ezrin, radixin, and moesin family and LIM domain-containing kinase (LIM-kinase) [9]. ROCKs seem to be involved in the effects of several vasoactive substances, including angiotensin II, thrombin, 5-hydroxytryptamine (5-HT), platelet-derived growth factor (PDGF) among others, all of which have been implicated in cardiovascular disease [9] . Furthermore, it has been suggested that some effects of statins are mediated by their inhibitory effects on Rho and thus the resultant block of ROCKs. Although, it has been shown that statins promote and activate endothelial nitric oxide synthase (eNOS) expression through inhibition of Rho, the extent to which therapeutic levels of statins inhibit Rho activity and, thereby, ROCK activity remains to be established [9].

Rho GTPases are associated with cell adhesion, motility, and contraction and seem to regulate cell proliferation and hypertrophy of the cardiomyocyte, gene expression, ion channel activity, endothelial permeability, and production of reactive oxygen species. The effects of certain members of the Rho family (i.e., RhoA) are mediated by Rho-dependent serine–threonine kinases (ROCK1 and ROCK2). This ROCK activity results in increased myosin phosphorylation and contraction, which could be associated with hypertension or coronary and vascular spasm [1]. Moreover, ROCK interaction with other signaling pathways results in PI3K inhibition, eNOS modulation, and activation of plasminogen activator inhibitor-1 (PAI1), all of which may contribute to endothelial dysfunction and atherogenesis [1]. Interestingly, some of the cardioprotective effects of statins that are independent of cholesterol could be related to ROCK inhibition [1]. Recent evidence also suggests that the phosphodiesterase inhibitor sildenafil inhibits functions mediated by ROCK in the pulmonary artery, having a beneficial effect on pulmonary hypertension. There is data to imply a beneficial effect of ROCK inhibition with Y-27632 and fasudil in I/R injury and myocardial infarction. In fact, ROCK antagonism in different experimental models of myocardial infarction, chronic hypertension, and congestive heart failure appears to reduce ischemia/reperfusion injury, infarct size, myocardial fibrosis, and cardiac hypertrophy. Additionally, it appears that ROCK inhibition leads to activation of the PI3-kinase/Akt/eNOS pathway, which results in cardiovascular protection. ROCK inhibition also prevents cardiac myocyte apoptosis and improves postischemic cardiac function [1].

In recent studies, ROCK1(+/–) haplo-insufficient mice had comparable basal and Ang II-stimulated blood pressure, heart rate, and cardiac dimensions in contrast to control mice, but showed considerably less perivascular fibrosis. Furthermore, after aortic banding ROCK1(–/–) homozygous mice revealed less perivascular and interstitial fibrosis associated with decreased expression of extracellular matrix proteins and fibrogenic cytokines [e.g., transforming growth factor-β2 (TGF-β2) and connective tissue growth factor]. These experimental models suggest that ROCK1 in response to pathological stimuli may contribute to the development of cardiac fibrosis but not hypertrophy [1].

### 1.6 Protein Kinase C (PKC) and Protein Kinase A (PKA)

The PKC family encompasses closely related serine–threonine kinases implicated in cell survival, proliferation, and apoptosis and plays a role in vasoconstriction, ischemic preconditioning, and cardiac hypertrophy. There is a tissue-specific expression pattern for the PKC isoforms, which have different subcellular distribution, targets, and cell function, as well as variable calcium and lipid sensitivity. However, the importance of each isoform in the cardiovascular system remains to be elucidated. It is known that PKC signaling pathways are set in motion by GPCRs with established cardiovascular effects, such as receptors for angiotensin II, Endothelin 1 (ET-1), phenylephrine, and neuron-hormonal ligands. Activation of some PKC isoforms could be beneficial, since PKC-ε may have a cytoprotective function in cardiac myocytes and PKC-ζ limits fibroblast hypoxia-induced proliferation by stopping ERK1/2 activation [1].

PKA is a ubiquitous serine–threonine protein kinase activated by cAMP that is of major importance for cellular function [10].

### 1.7 Calcium/Calmodulin-Dependent Protein Kinase II (CaMKII)

CaMKII is one of several specialized proteins that modulates or responds to calcium signaling in myocytes, and there is evidence that associates CaMKII to both physiological and pathological conditions in the heart. It has been shown that CaMKII phosphorylates multiple proteins that share consensus motifs that contain serine or threonine. Thus, CaMKII articulates changes in calcium cycling at multiple levels, including (1) regulation of L-type calcium channels (LTCC) and thus calcium entry into the cell, (2) modulation of ryanodine receptors (RyR) and thus calcium release from the sarcoplasmic

reticulum (SR) stores, and (3) changes of the sarcoplasmic/endoplasmic reticulum calcium-ATPase (SERCA) and thus SR calcium uptake. There are four genes encoding CaMKII subunits (α, β, γ, and δ) with highly identical catalytic and regulatory domains, but so far only γ and δ have been detected in the heart, being CaMKIIδ the predominant isoform in the mammalian heart [11].

Certain parts of the regulatory domain bind to the catalytic domain in the absence of calcium, occluding thereby the binding of nucleotides and protein substrates. When calcium/calmodulin binds to the regulatory domain, apparently there is a change in protein conformation and this activation occurs to a different extent depending on the frequency, amplitude, and duration of the calcium transients. The kinase capacity to sustain its activity through autophosphorylation, even in the absence of increased calcium/calmodulin, renders notable flexibility for extending CaMKII-dependent regulation over time. Thus, CaMKII integrates and regulates calcium cycling in the cell and translates these changes to transcriptional tasks that are crucial for the contractile apparatus in cardiac myocytes [11].

### 1.8 Mammalian Target of Rapamycin (mTOR)

The serine–threonine kinase mTOR is activated through stimulation by ATP, hypoxia, growth factors, and other elements that modulate cell growth and division. A number of signaling pathways that are upstream of mTOR, such as ERK1/2 and PI3K, are involved in cardiac hypertrophy. In fact, mTOR inhibition by rapamycin appears to attenuate and overturn cardiac hypertrophy in experimental pressure overload models [1].

### 1.9 Glycogen Synthase Kinase-3β (GSK3β)

GSK3 phosphorylates serine–threonine residues, which can change the biological activity of the substrate or can prime some substrates (e.g., β-catenin and c-MYC) for proteasome destruction. GSK3 has several physiological substrates, such as transcription factors and regulators of metabolism. As with other kinases, GSK3 activity is controlled by it own phosphorylation at a tyrosine residue, and in mammalian cells, this seems to be mediated by an autophosphorylating event that is important for enzyme stabilization. Even when it has been suggested that the tyrosine phosphorylation of GSK3 changes in response to extracellular signals, it is now said that GSK3 is inhibited by a variety of agonists because of phosphorylation of a serine residue [12]. GSK3β positively regulates apoptosis and negatively regulates hypertrophy in the heart. In endothelial cells GSK3β signaling is associated with angiogenesis. In contrast to other protein kinases, phosphorylated GSK3β is inactive and vice versa. Active GSK3β stimulates factors involved in protein synthesis (e.g., elF2B) and expression of genes related to hypertrophy (e.g., c-MYC, GATA4, β-catenin). There is evidence that GSK3β inhibition reduces myocardial cell death after I/R [1].

GSK3β inhibitors (such as lithium and SB216763) can mimic angiogenesis and cardioprotection mediated by ischemic preconditioning in rats. In addition, GSK3β antagonism could have therapeutic applications requiring angiogenesis since inactivation of the GSK3β gene in human endothelial progenitor cells appears to increase angiogenic cytokine secretion, such as vascular endothelial growth factor (VEGF) and interleukin-8, and is associated with enhanced survival, proliferation, and differentiation of these cells. Furthermore, genetically modified cell transplantation into ischemic hind limbs of mice has been shown to improve blood flow, limb salvage, and tissue capillary density. On the other hand, ischemia followed by administration of volatile anesthetics seems to activate salvage kinases and lessen reperfusion injury. Isoflurane protects against reperfusion damage by blocking GSK3β. In addition, it has been described that local kallikrein gene delivery in I/R involves GSK3β, which promotes cardiac myocyte survival. Short-term antagonism of GSK3β in myocardial ischemia may be useful, and further investigation in this field is required [1]. There has been some concern that chronic inhibition of GSK3β might promote the appearance of cardiac hypertrophy since this kinase has been described as having an antihypertrophic role. However, there is data suggesting that chronic GSK3β inhibition with lithium does not appear to favor cardiac hypertrophy. A number of selective and potent inhibitors of GSK3β have been identified, and further evidence is needed to define their potential in this specific therapeutic setting [1].

### 1.10 5′-AMP-Activated Protein Kinase (AMPK)

Since the early 1970s, AMPK has been recognized as an AMP-dependent kinase that inactivates 3-Hydroxy-3-methyl-glutaryl-Coenzime A (HMGCoA) reductase and acetyl-CoA carboxylase (ACC), which works as a cellular fuel sensor, that is activated when energy availability is reduced and AMP levels are relatively high, and decreases anabolic processes such as lipogenesis while enhancing glucose uptake [4]. Recently, AMPK has been recognized as an important regulator of energy homeostasis in the cell and coordinator of multiple catabolic and anabolic pathways in the heart. Several pathophysiological conditions such as ischemia, hypertrophy, diabetes, and certain forms of cardiomyopathies are associated with alterations in fatty acid and glucose metabolism, partly secondary to alterations in regulatory proteins. It is thought that in the heart, chronic

variations in energy substrate utilization involve shifts in acute control mechanisms, such as phosphorylation/dephosphorylation of key proteins, being AMPK centrally involved. In fact, it has been shown that acute increases in workload appear to activate AMPK due to increases in AMP levels, which seems to favor energy-generating pathways to maintain or restore intracellular ATP levels. Under acute conditions, such as mild ischemia or short intervals of severe ischemia, cardiac AMPK activation appears to stimulate ATP generation via increased glycolysis and accelerated fatty acid oxidation, thus being necessary for myocyte function and survival. AMPK seems to mediate the uptake and utilization of fatty acids by the heart via a number of processes, such as recruitment of cardiac lipoprotein lipase to the coronary lumen, translocation of the fatty acid transport protein CD36 (cluster of differentiation 36) from intracellular compartments to the plasma membrane, phosphorylation and subsequent inhibition of ACC, thus favoring the import of fatty acyl CoA into the mitochondria, which results in enhanced β-oxidation of fatty acids and subsequent ATP generation. Therefore, AMPK is a key mediator of fatty acid utilization in the heart by promoting fatty acid availability, fatty acid transport, and fatty acid oxidation [13, 14]. Several upstream AMPK kinases (AMPKKs) that potentially regulate its activity have been identified, such as serine/threonine kinase 11 (LKB1) and the calcium/calmodulin-dependent protein kinase kinases (CaMKKs α and β) among others. Defining their role in the heart will contribute to an increased understanding of cardiac AMPK regulation [13].

While AMPK activation may be crucial for adjustment of cardiac energy metabolism during acute and/or minor metabolic stresses, it is not known whether activation of this kinase turns out to be maladaptive in certain chronic disease states and/or during excessive energetic stress. In fact, changes in cardiac AMPK activity have been associated with cardiac hypertrophy, ischemia, glycogen storage cardiomyopathy, and Wolff–Parkinson–White syndrome. Since it is known that heart failure, myocardial ischemia and hypertrophy, diabetic cardiomyopathy, and lipotoxic heart disease are associated with changes in cardiac energy metabolism, and it has been established that AMPK is an important modulator of cardiac energy metabolism, directed AMPK regulation may be relevant in these pathological settings. Different stimuli, such as hyperosmotic stress, exercise, hypoxia, ischemia, leptin, adiponectin, alfa-adrenergic receptors, metformin, and long-chain fatty acids, activate AMPK [13, 14].

Basically, AMPK stimulation seems to be advantageous to the heart through the activation of energy-generating pathways and inhibition of energy-consuming pathways. In order to maintain constant ATP levels for proper cardiac function, activated AMPK increases energy-production by increasing fatty acid uptake and oxidation, stimulating glucose uptake, and favoring glycolysis, while decreasing protein synthesis and possibly lipid synthesis. Inhibition of energy-consuming pathways in a healthy heart that is metabolically stressed probably plays a minor role in maintaining mechanical function, whereas it may be more relevant in chronically or severely stressed hearts. AMPK regulates cardiac glucose utilization by stimulating glucose uptake, glycolysis, and possibly glycogen metabolism. Activation of cardiac AMPK appears to promote glucose transporter (GLUT) translocation to the myocyte membrane in an insulin-independent manner, and it may also favor GLUT4 to be retained in the sarcolemma, thus increasing overall GLUT4 levels in the plasma membrane [13, 14]. Inhibition of energy-consuming pathways that are not essential in an energetically compromised heart, such as protein synthesis, allows directing ATP toward crucial cellular processes such as contractile function and ion homeostasis [13].

### 1.11 Other Protein Kinases

The family of lysine deficient protein kinases (WNK) serine–threonine kinases has been shown to play an essential role in the regulation of electrolyte homeostasis [15]. It appears that WNK1 and WNK4 control diverse transcellular ion transport pathways and inhibit the thiazide-sensitive sodium/chloride cotransporter and the renal outer medullar potassium channel in the kidney. Furthermore, WNK4 seems to be localized to tight junctions and might also regulate paracellular ion flux. In the kidney, WNKs have been described to act as a molecular switch that allows alternating between sodium/chloride reabsorption and potassium secretion. In extrarenal epithelia, WNK4 seems to regulate other ion transporters and exchangers, suggesting pleiotropic roles for this kinase [15, 16].

## 2 PROTEIN KINASE-MEDIATED SIGNALING IN CARDIAC PATHOLOGY: A NOVEL THERAPEUTIC TARGET?

In response to diverse stresses, there are changes in cellular architecture, and increased activity of cytokines, catecholamines, and angiotensin signaling that initiate raised protein kinase activity in structural heart disease [2].

### 2.1 Cell Signaling in Hypertension

***Systemic Hypertension*** There is evidence that ROCKs in the brain stem contribute to regulate blood pressure

through the sympathetic nervous system [9]. Also in vascular smooth muscle cells, different stimuli, such as growth factors, cytokines, vasoconstrictors, and mechanical stretch, trigger intracellular signal transduction involving the epidermal growth factor receptor (EGFR), small G-proteins, and MAPKs [7]. Rho and ROCK have been implicated as mediators of enhanced contraction, hypertrophy, and migration of vascular smooth muscle cells and inhibition of endothelial function [7].

PKC antagonists could be valuable in the treatment of hypertension, especially when combined with ROCK inhibitors, since both enzymes have been described to play a relevant role in vasoconstriction at the arterial level. Interestingly, in small arteries PKC appears to regulate vasoconstriction without evident contribution of ROCK, and the nonspecific PKC inhibitor Ro 31-8220 seems to potentiate the vascular effects of calcium channel blockers [1].

There is data suggesting that pseudohypoaldosteronism type II (PHAII) might be related to mutations in two members of the WNK family of serine–threonine kinases, with evidence supporting a genetic gain of function mechanism. The kinases WNK1 and WNK4 are localized in distal nephron segments and are known to play a role in the homeostasis of electrolytes that are altered in PHAII. In fact, certain individuals with essential hypertension that have low plasma renin activity and respond well to thiazide diuretics might have WNK1 and WNK4 variants that underlie blood pressure variations. Therefore, WNK kinases and/or other components of their signaling pathway in the kidney may be potential new targets for the development of antihypertensive diuretic drugs [15–17].

***Pulmonary Arterial Hypertension*** Primary pulmonary hypertension is a fatal disease associated with endothelial dysfunction, increased contraction and proliferation of VSMCs, and inflammatory changes for which there is no definitive treatment available. Most therapeutic approaches for pulmonary hypertension including oral anticoagulants, vasodilators (prostaglandins, sildenafil, bosentan), and lung transplant have mixed clinical results leaving space for more effective therapeutic options to be developed. ROCK has been associated with vascular constriction and remodeling through myosin phosphatase inhibition and activation of downstream activators. Furthermore ROCK has been suggested to be an important mediator of arteriosclerosis and a couple of animal models of pulmonary hypertension have been reported to present ROCK activation. In fact, in these studies ROCK has been associated with enhanced pulmonary vasoconstriction and proliferating responses, endothelial dysfunction, and pulmonary remodeling [18].

### 2.2 Acute Coronary Syndromes and Stroke: Molecular Changes During Ischemia

There is evidence showing that myocardial ischemia induces activation of AMPK, although the consequences are still unclear. It is thought that AMPK is necessary for adiponectin's protective effect against I/R injury, and AMPK may activate downstream pathways. In fact, AMPK activates p38-MAPK in the heart, which may contribute to increased glucose uptake, and increased glucose utilization mediated by AMPK seems to be beneficial during and following ischemia. In transgenic mouse lines, targeted deletion of AMPK does not induce an obvious cardiac phenotype under normal workload, but glucose uptake is not increased in response to ischemia-reperfusion, which is probably related to insufficient GLUT4 translocation to the cell membrane. However, AMPK activation could be disadvantageous for the postischemic recovery. During ischemic episodes, oxidative metabolism is restrained while glucose uptake is amplified and glycolysis is increased. During the reperfusion period following mild ischemia or short intervals of severe ischemia, contractile function recovers when energy production has been reinstated. Even though there are many mechanisms that contribute to ischemic injury, recovery depends partly on the kind of substrate metabolized by the heart upon reperfusion. During ischemia fatty acid levels are elevated, and high fatty acid plasma levels are detrimental to both the ischemic and the reperfused heart. Furthermore, AMPK is activated during myocardial ischemia, which leads to phosphorylation and inhibition of ACC, increased GLUT4 levels in the cell membrane, and activation of PFK-2. Thus, activated AMPK increases ATP supplies overall through fatty acid oxidation and glycolysis. However, high rates of β-oxidation inhibit glucose oxidation rates via inhibition of the pyruvate dehydrogenase complex, and this eventually causes an imbalance between glucose oxidation and glycolysis with lactate and proton accumulation. It was originally proposed that activation of AMPK induced by ischemia favors a series of metabolic events that might be unfavorable to recovery of contractile function during reperfusion.

Although evidence from transgenic animals suggests that enhanced glucose uptake by AMPK may protect against ischemia/reperfusion injury, especially if the potentially negative consequences of increased fatty acid oxidation are not present. Therefore, further research in the area is necessary in order to understand whether AMPK activation is beneficial or detrimental to the I/R heart [13]. There is evidence using bovine brain microvessels that shows that endothelial cells subjected to stroke conditions have increased PKC-α, -β, and -ε levels and decreased PKC-γ after 6 h of hypoxia/

aglycemia. In this experimental model, PKC-α, -β, and -ε inhibition appears to downregulate the activity of the Na,K,2Cl-cotransporter (NKCC), and the use of a conventional PKC activator seems to upregulate it. These results imply that specific PKC inhibition or activation might impact outcome in stroke by brain ion transport [1].

A myocardial infarct model in rats provided evidence showing that treatment with LY333531 prevents reduced fractional shortening, increased matrix deposition and expression of TGF-β, which could be beneficial in preventing heart failure after infarction [1].

MAPKs are activated during ischemia/reperfusion injury and appear to contribute to structural as well as functional changes associated with myocardial ischemia, and evidence suggests that ERK1/ERK2 mediate survival pathway while p38 and JNK regulate a death pathway. It appears that cardiac protection dependent on ischemic preconditioning is associated with p38 activation, and direct p38 and JNK stimulation with anisomycin has also a protective effect. These contrasting effects may be explained by the activation of different p38 isoforms since p38α acts as proapoptotic, whereas p38β acts antiapoptotic in rat neonatal ventricular myocytes [19].

### 2.3 Atherosclerosis and Vascular Remodeling

The ROCK signaling pathway is known as a major modulator of vascular smooth muscle cell (VSMC) contraction, cell migration, proliferation, differentiation, as well as apoptosis, cell survival, and gene transcription [9]. This pathway seems to be involved in the regulation of endothelial barrier function, transendothelial leukocyte migration and inflammation, platelet activation and thrombosis, and oxidative stress. Activation of ROCK decreases eNOS expression by favoring eNOS messenger ribonucleic acid (mRNA) instability, since direct inhibition of Rho or inhibition of ROCK by hydroxyfasudil or overexpression of dominant-negative ROCK prevents eNOS downregulation [9]. It has been suggested that JNK could be a key mediator of atherosclerosis, since it has been shown that transfection with a dominant-negative JNK gene blocks neointimal formation in vivo and deletion of JNK2 in macrophages reduces atherosclerosis in mice. Furthermore, there is evidence showing that JNK2 promotes foam cell formation mediated by scavenger receptor A, which is associated with early atherogenesis. There is evidence that suggests that intimal hyperplasia after balloon injury in rat carotid artery can be inhibited by adenoviral gene delivery of dominant-negative ERK. In addition, the compound PD0185625, an oral selective ERK1/2 (p42/p44MAPK) inhibitor, may represent a novel therapeutic approach for vascular remodeling, since it appears to reduce neointimal formation after arterial injury [7].

### 2.4 Regulation of Platelet Function by Protein Kinases

After tissue injury, some effects of PI3Kγ seen in platelet aggregation and thrombus formation are apparently independent of chemokine receptors. It is well known that platelets respond to a wide range of GPCR agonists that activate PI3K signaling, such as thrombin, thromboxane, and ADP. However, PI3Kγ-deficient thrombocytes apparently have a normal response to both thrombin and thromboxane but show decreased aggregation when stimulated with ADP. This might be related to the fact that in platelets PI3Kγ is associated with the ADP receptor P2Y12, but not with the thrombin receptor, even if all three molecules are co-expressed in the same cell. Furthermore, PI3Kγ-deficient mice show normal bleeding time but have a decreased mortality rate in a model of ADP-induced thromboembolism [5].

Human platelets express all 4 p38 MAPK isoforms, and p38 α and β are the most abundant, although the exact role of these kinases in platelet function remains unclear. Different platelet agonists have been described to activate p38 in platelets. For example, in vitro stimulation of normal platelets with thrombin, collagen, and U46619, but not ristocetin, has been reported to result in strong p38 activation. However, it seems that platelet aggregation in this setting cannot be prevented by pretreatment with the p38 inhibitor VX-702. Even when it has been suggested that a potential role of p38 is to activate phospholipase A2, which triggers arachidonic acid metabolism and thus production of thromboxane, there is evidence that shows VX-702 has no effect on collagen-induced platelet aggregation (i.e., dependent on thromboxane production). Therefore, p38 block does not significantly affect platelet function and is not expected to be associated with elevated risk of bleeding [20].

### 2.5 Protein Phosphorylation and Cell Growth Regulation in Cardiac Hypertrophy and Heart Failure

Heart failure is a clinical syndrome initiated by a primary myocardial injury with subsequent activation of response mechanisms in the heart, vasculature, and neural and hormonal systems. Even though most of these mechanisms are initially compensatory, eventually many contribute to further worsening of heart function and progression of symptomatology. Currently, it has been shown that inhibition of the increased sympathetic nervous system and the renin–angiotensin system is a crucial element in the treatment of heart failure with a

positive effect on survival [21]. Therefore, it may be attractive to explore alternative antagonism of downstream elements of these pathways as therapeutic options in the management of these patients. However, it is difficult to single out the effects of specific signaling pathways, their intensity and duration of activation, and the potential adverse synergies when a given stimulus is considered as adaptive or maladaptive [22]. Furthermore, it is known that multiple pathways are involved in hypertrophic signaling, and these signaling networks are highly interconnected. It is common that alterations in one signaling pathway have consequences in other signaling cascades.

ERK1/2 appears to favor compensatory hypertrophy. JNK and p38MAPK activation is linked with both cardiac hypertrophy and apoptosis [1, 22, 23]. In fact, p38 activation in the heart has been observed in ischemia or pressure-overload-induced hypertrophy and heart failure. Furthermore, activation of p38 appears to decrease cell contractility by depressing myofilament response to intracellular calcium [23]. In fact, all MAPK-dependent signaling pathways appear to trigger a final common hypertrophic molecular program where the transcription factor myocyte-enhancing factor 2 (MEF2) participates [21].

Rho-kinase, which has been associated with the hypertrophic process in the heart since inhibition with fasudil, inhibits left-ventricular remodeling in experimental myocardial infarction [21]. It has been shown that ROCK is involved in left-ventricular remodeling after myocardial infarction (MI) by favoring the presence of pro-inflammatory cytokines, suggesting the therapeutic relevance of ROCK in preventing post-MI heart failure [9]. Furthermore, in response to pressure overload ROCK1-deficient (ROCK1–/–) mice had preserved compensatory hypertrophy but presented lower levels of perivascular and interstitial fibrosis. In addition, ROCK1-haploinsufficient (ROCK1+/–) mice showed in response to pressure overload cardiac fibrosis without hypertrophy [9]. ROCK's contribution to the development of cardiac hypertrophy is associated with enhanced oxidative stress by upregulation of endothelial reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and endothelial dysfunction [9].

CaMKII is upregulated in different models of cardiac hypertrophy and contributes to the loss of calcium homeostasis, typically seen during cardiac hypertrophy [24]. Transgenic mice overexpressing CaMK in the heart have severe cardiomyopathy [11]. Furthermore, CaMKIIδ overexpression causes cardiomyocyte hypertrophy, electrical remodeling, and arrhythmias [24]. In fact, when CaMKII is overexpressed in transgenic mouse hearts, it is associated with a prolonged calcium transient, enhanced L-type calcium currents, ryanodine receptor calcium leak, and loss of contractile function. The augmented ryanodine receptor leak due to PKA hyperphosphorylation is linked to structural heart disease in animal models and in patients [24]. In addition, the α-adrenergic signaling cascade activates CaMKII by a mechanism requiring PKC activation and turns on genes involved in cardiac hypertrophy, which is prevented by CaMKII inhibition [11].

In cardiac hypertrophy induced by either pressure or volume overload, energy metabolism is usually changed in order to reduce overall oxidative metabolism and increase glycolysis. Some of these alterations have been attributed to changes in expression of certain genes, and AMPK has been proposed to be directly responsible for increasing glycolysis via PFK-2 regulation. Apparently, switching to a more glycolytic state seems to be an adaptive response to chronic reduction in myocardial perfusion, which results from increased myocyte cell size. However, as the hypertrophic process advances, reductions in fatty acid oxidation may eventually deprive the heart of energy, and thus be considered as maladaptive. Even though, it is said that AMPK may also regulate other mediators of hypertrophy such as protein synthesis, its role in regulating cardiac myocyte growth remains controversial. In fact, while some studies show a correlation between AMPK activation and development of cardiac hypertrophy, other studies show hypertrophic growth inhibition mediated by AMPK activation [13, 14]. Mutations in human AMPK (γ subunit), which inhibit activation of AMPK by AMP, have been linked to hypertrophic cardiomyopathy. The AMPK mutation could lead to increased glycogen synthase activity, increased glycogen production, and the observed accumulation of glycogen in the heart [4, 14].

The role of mTOR in cardiac hypertrophy has been established after using its antagonist rapamycin to reduce this condition [21]. However, even when mTOR inhibition could be therapeutically attractive for the treatment of pathological hypertrophy, blocking other members of this pathway could have contrasting effects. For example, inhibition of AKT or PI3K (phosphatidyl inositol 3-kinase) under certain settings may not be advantageous because they modulate physiological and adaptive hypertrophy, which may be beneficial [22]. Transgenic mice that have chronic activation of Akt develop cardiac hypertrophy, which could be mediated through several mechanisms, including activation of molecules involved in protein synthesis, such as mTOR. Since Akt activation negatively regulates AMPK activity in the heart and pharmacological activation of AMPK attenuates cardiac hypertrophic growth and protein synthesis induced by constitutively active Akt, it has been proposed that inactivation of AMPK by Akt promotes protein synthesis in the hypertrophic myocardium. However, there are mouse models with impaired

AMPK activity that have normal or smaller heart weights compared to control hearts, which rejects AMPK inactivation as being essential for hypertrophic growth. Thus, despite the fact that AMPK activation prevents cardiac hypertrophy, further proof is needed to define whether AMPK is a necessary component of the hypertrophic signaling cascade. In fact, it is not known whether decreased AMPK activity renders the heart more susceptible to hypertrophic growth stimuli. On the other hand, adiponectin-deficient mice have decreased AMPK signaling and are more susceptible to pressure-overload-induced cardiac hypertrophy. Furthermore, adiponectin reversed the severity of cardiac hypertrophy in these animals and restored AMPK signaling, whereas expression of an AMPK-dominant negative mutant blocked the beneficial effects. However, it is not known whether AMPK's direct role in the hypertrophic process seen in adiponectin-deficient mice is relevant in other models of cardiac hypertrophy [13, 14]. Indeed, it has been suggested that activators of AMPK such as adiponectin, metformin, or thiazolidinediones may be used to prevent hypertrophic growth, even though the doses of metformin needed to activate AMPK in vitro are considerably higher than those seen clinically. Thus, it is thought that more specific compounds are needed in order to explore the value of AMPK activators for the prevention of cardiac hypertrophy [13].

Several animal models have linked PI3K with cardiac hypertrophy and ischemia and imply a specific role for the different isoforms. For example, it appears that PI3K is activated during ischemia and pressure overload. Furthermore, overexpression of PI3Kα, one of the isoforms activated by receptor tyrosine kinases, produces compensatory hypertrophy without cardiac dysfunction, while activation of PI3Kγ induces hypertrophy followed by heart failure. In fact, activation of receptor tyrosine kinases results in adaptive hypertrophy via PI3Kα, while stimulation of GPCRs and PI3Kγ causes maladaptive cardiac hypertrophy. In vivo PI3Kα inhibition seems to negatively modulate heart size while PI3Kγ inhibition appears to negatively modulate cardiac contractility [1].

The progress in basic science has clearly expanded the range of possible therapeutic targets for heart failure [21]. The use of mouse models of cardiomyopathy has provided new knowledge about the cellular and molecular basis of heart failure, which exposes a large number of potential targets for pharmacotherapy or gene therapy. Nonetheless, most studies and therapies used clinically to treat heart failure have mainly targeted cell surface receptors or the intracellular mineralocorticoid receptor. The specific targeting of intracellular signaling pathways is a promising new approach for drug development. Even when small-molecule inhibitors are available for pathways that contribute to myocyte hypertrophy in the heart, the use of these compounds is limited by their poor cardiac selectivity and associated toxicity [21].

### 2.6 Metabolic Syndrome, Diabetes, and Hyperlipidemia

Activators of AMPK could be useful to treat metabolic syndrome, diabetes, or hyperlipidemia [4] since there is evidence in vitro and in vivo showing that inactivation of hepatic AMPK is a key event in the pathogenesis of hyperlipidemia in diabetes [25]. In fact, AMPK inhibition has been observed in pancreatic cell lines exposed to elevated glucose [26], in the hearts of obese Zucker diabetic fatty rats and ob/ob mice [27], and in cultured human skeletal muscle of obese type II diabetic patients [28]. There is also evidence suggesting that class IA PI3K signaling is necessary to mediate insulin functions in vivo, and the loss of activity in this kinase could cause complex metabolic defects that may be linked to type II diabetes [5]. Furthermore, insulin favors glucose uptake into muscle by glucose transporter GLUT4 translocation to the plasma membrane, which is mediated by a PI3K-dependent pathway that requires AKT (i.e., the β isoform of protein kinase B) [12].

Overexpression of PKC-β (but not PKC-α, -δ, or -ζ) in rat endothelial cells was shown to decrease insulin and VEGF-induced Akt activation and eNOS expression. Studies in transgenic mice suggest that PKC-β activation in endothelial cells and vascular tissue appears to inhibit Akt-mediated eNOS regulation by insulin, and causes endothelial dysfunction associated with insulin resistance and obesity. Furthermore, in healthy humans PKC-β inhibition with LY333531 seems to prevent the decrease in endothelium-mediated vasodilation associated with acute hyperglycemia. This data suggests that hyperglycemia may impair endothelial function by mechanisms that involve PKC-β [1].

Studies in streptozotocin-induced type I diabetes suggest that oxidative stress and PKCβ2 related to chronic hyperglycemia may participate in the development of cardiomyopathy, since diabetic rat hearts appear to have increased expression of PKCb2 with concomitant myocyte hypertrophy and cardiac fibrosis. In addition, in vitro results show that nonspecific activation of PKC is enough to induce the same degree of hypertrophy as hyperglycemia. In fact, hypertrophy induced by a PKC activator (phorbol 12-myristate 13-acetate [PMA]) in cultured neonatal cardiomyocytes appears to be prevented by specific PKCβ2 inhibition, but not by PKCd antagonism; thus PKCb2 may be a prohypertrophic signal. However, specific PKCβ2 inhibition attenuates but does not completely prevent cardiomyocyte hypertrophy induced by hyperglycemia [29].

JNK activity is also elevated in obesity and diabetes. In two different models of murine obesity, the absence of JNK1 appears to result in decreased adiposity with improved insulin sensitivity and enhanced signaling capacity of the insulin receptor. Moreover, JNK2 has been linked to type I diabetes since deletion of JNK2 (knockout) in nonobese diabetic mice seems to reduce disease progression and development of type I diabetes. It has been suggested that JNK2 activity participates in controlling the immune response balance and represents a protecting mechanism against autoimmune diabetes [7].

### 2.7 Arrhythmias

There is evidence that increased and disordered intracellular calcium plays a role in arrhythmogenesis. In fact, loss of normal intracellular calcium homeostasis occurs in almost all forms of cardiac disease associated with fatal arrhythmias [24, 30]. For example, arrhythmias following drug-related excessive prolongation of repolarization (long QT syndromes) or electrical remodeling in cardiomyopathy are linked to disordered intracellular calcium. Moreover, ventricular fibrillation triggered by ischemia is also coupled with deregulation of intracellular calcium. However, even when intracellular calcium is consistently linked to arrhythmias, increases in calcium levels alone may not be sufficient to set off arrhythmias since it appears that a further step is required, where a calcium-sensing protein translates it into distorted cellular function [30].

The ubiquitous serine–threonine protein kinase CaMKII has been implicated in arrhythmogenesis and structural heart disease since CaMKII appears to be involved in regulating atrioventricular (AV) nodal conduction, and CaMKII activity and expression are higher in hearts prone to arrhythmia. Additionally, overexpression of CaMKII in the heart favors the development of cardiac hypertrophy, dysfunction, and proarrhythmogenic remodeling, while CaMKII inhibition decreases arrhythmias [1]. CaMKII has been recognized as a proarrhythmic signaling molecule since it can orchestrate arrhythmia signaling through ion channel proteins, intracellular calcium uptake and release, regulation of cell death, and activation of prohypertrophic pathways. CaMKII shares many of the same downstream protein targets as PKA, which is the kinase most associated with β-adrenergic receptor stimulation [24]. It has been described that calcium, calmodulin, and CaMKII interact in the feedback mechanisms for LTCC regulation, cardiac contraction, and arrhythmias in model systems involving smooth muscle as well as cardiac myocytes. Modulation of LTCC is critical for calcium homeostasis and signaling; thus defective LTCC regulation contributes to disease states associated with abnormal levels of calcium influx. In addition, CaMKII-induced phosphorylation favors channels to be in a high-activity gating mode, which leads to prolonged opening. Besides, CaMKII modulates calcium release via RyR since a CaMK inhibitor (peptide AC3I) enhances RyR calcium release while blocking calcium currents in acutely isolated rabbit cardiac myocytes, thus enhancing the gain of excitation-contraction coupling. In fact, addition of a constitutively active CaMKII yields the opposite result, suggesting that this kinase could be a functional link between LTCC and RyR during excitation-contraction coupling. Cardiac overexpression of CaMKIIδ in transgenic mice is associated with myocardial hypertrophy, left-ventricular chamber dilation, loss of normal contractile function, proarrhythmic electrical remodeling, and sudden death [11, 24].

Chronic overexpression of CaMKIIδ generates altered calcium handling with enhanced calcium sparks from the RyR, reduced SR content, and severe cardiac hypertrophy. This could be a direct result or an indirect result through changes in the protein level of other key calcium-cycling proteins associated with CaMKII overexpression, such as a decrease in SERCA and phospholamban (PLB) and an increase in the Na/Ca exchanger. Thus, even though CaMKII is an important regulator of intracellular calcium release, details of this process remain to be elucidated. It has been suggested that enhanced RyR calcium leak or proarrhythmic inward calcium current due to altered CaMKII activity can lead to increased Na/Ca exchanger activity, thus favoring the probability of producing delayed afterdepolarization. Another trigger for arrhythmias is stimulation by the β-adrenergic pathway, which leads to increased heart rate and which recruits CaMKII and enhances calcium cycling. These findings suggest that the efficacy of beta-blockers in preventing sudden cardiac death may be in part related to their inhibition of CaMKII activity [11].

It has been proposed that CaMKII directly regulates SERCA activity and phosphorylates PLB, and physiological increases in phosphorylation by CaMKII probably follow catecholamine-stimulated chronotropic and inotropic changes. Consequently, this could correlate with an adaptive response to sudden modifications in heart rate. In fact, chronic CaMKII inhibition apparently reduces the variability of calcium-induced calcium release in cardiac myocytes by regulating calcium release from SR stores and calcium reuptake by SERCA [11]. CaMKII upregulation may be associated with increased activity of calcium channels and arrhythmias in heart failure [24].

Pharmacologic probes, such as W-7, block calmodulin action and appear to suppress torsades de pointes in a rabbit model without shortening the QT interval.

Furthermore, in patients taking amiodarone, which is a calmodulin antagonist, there is a relative lack of proarrhythmia that follows QT interval prolongation suggesting that calcium-bound calmodulin is involved in triggering torsades de pointes [30].

Interestingly, mutations in human AMPK (γ subunit) have been linked to ventricular pre-excitation [4, 13]. These mutations appear to be linked to the development of hypertrophic cardiomyopathy associated with excessive glycogen storage and the Wolff–Parkinson–White syndrome. In fact, patients with mutations in the AMPK γ2 gene show a familial form of the Wolff–Parkinson–White syndrome with characteristic conduction system abnormalities that might be related to altered AMPK activity. Altered AMPK activity seems to be accountable for excessive glycogen deposition within the cardiac myocytes, which favors bypass tracts that lead to the development of the arrhythmia. However, altered AMPK activity might also have an effect on other targets, such as ion channels, since AMPK activation augments hH1 sodium channel activity in cardiac myocytes. It has also been determined that several of these naturally occurring mutations in the human γ2 subunit do not lead to constitutively active AMPK enzymes but alter AMP's ability to stimulate AMPK. Furthermore, transgenic mouse lines expressing these mutations in a heart-specific manner have consistent phenotypes with those of humans that have mutations in the γ2 subunit. However, the presence of higher levels of the γ2 subunit alone appear to have effects on the cardiac myocyte since control mice expressing the nonmutated subunit had no changes in AMPK activity but also developed increased glycogen deposition [13]. Contrasting results make it difficult to conclude whether deregulation of AMPK activity contributes directly to the development of Wolff–Parkinson–White syndrome. Transgenic mice with two different mutations in the γ2 subunit appear to have opposing effects on AMPK activity in vivo with almost identical phenotypes. It is proposed that AMPK-activating mutations promote glycogen accumulation by increasing glucose uptake surpassing glucose utilization, whereas AMPK-inactivating mutations enhance glycogen deposition by increasing glycogen synthesis. Furthermore, transgenic mice with the R531G mutation develop a progressive cardiac phenotype with normal function and AMPK activity in early life but with cardiac hypertrophy, significant glycogen accumulation, and reduced AMPK activity at 4 weeks of age. Therefore, simple loss or gain of function in AMPK does not explain the pathogenesis of the Wolff–Parkinson–White syndrome since the altered AMPK activity in these mice develops gradually and likely following glycogen buildup. As a result, deregulation of AMPK activity appears to contribute to the development of disease but further studies are needed to clarify this [13].

Several in vivo studies using transgenic mice suggest that CaMKII targets the LTCC and that CaMKII inhibition might reduce arrhythmias related to increased probability of LTCC opening. However, increases in LTCC opening do not appear to be the only proarrhythmogenic mechanism associated with CaMKII, and compensatory responses to chronic CaMKII inhibition are not predictable, and patients placed on chronic CaMKII blockade might exhibit compensatory responses, such as reverse electrical remodeling [24].

Finally, atrial tissue from patients with atrial fibrillation has been shown to present CaMKII upregulation with CaMKII-induced hyperphosphorylation of phospholamban when compared to control patients in sinus rhythm. In addition, it has been described that CaMKII activity seems to be important for stimulating the atrioventricular node impulse transmission at baseline and in response to catecholamine stimulation. Therefore, CaMKII inhibition could be used for ventricular rate control in the setting of atrial fibrillation. However, it is not known if CaMKII antagonism can affect atrial fibrillation [24].

## 3 STRUCTURAL AND FUNCTIONAL BIOLOGY OF PROTEIN KINASES IN THE HEART AND VASCULATURE: MODULATION IN CARDIOVASCULAR DISEASE

Protein kinases play a central role in signal transduction, and most aspects of cell life are controlled by the reversible phosphorylation of proteins. The development of specific, cell-permeable protein kinase antagonists has been crucial in the study of signal transduction processes so far, and they have been extensively used to establish the relevance and involvement of a particular protein kinase in health and disease. The main challenges in designing protein kinase inhibitors are (1) to understand what determines its selectivity and (2) being able to select the appropriate clinical setting where its use could potentially be beneficial with an adequate safety and efficacy profile. The great number of protein kinases, their close structural and sequence similarity, and their involvement in normal cell function complicate the design and use of compounds that target these proteins as therapeutic options in cardiovascular disease. Even though the availability of many kinase crystal structures has improved our knowledge of factors that determine selectivity at the molecular level, many small-molecule kinase inhibitors do not seem to reach optimal selectivity. Most clinical trials with protein kinase inhibitors are mainly in oncology; however, there

is a trend toward targeting protein kinases for the treatment of a number of chronic conditions other than cancer, including inflammatory and cardiovascular diseases [4].

### 3.1 Mitogen-Activated Protein Kinase (MAPK) Pathways

It is known that p38 inhibitors have anti-inflammatory effects in different animal models primarily by decreasing the expression of inflammatory mediators. Consequently, several p38 inhibitors have been evaluated in preclinical or clinical studies. Nevertheless, the recurring failure of p38 inhibitors in the clinic suggests that new approaches are needed for designing p38 antagonists. Pyridinyl imidazole inhibitors have been important to identify and characterize the p38 pathway, and with subsequent variation of the original structures several drug candidates such as SB203580 emerged. These first-generation antagonists, though, have been found to be hepatotoxic and potential carcinogens. There are other inhibitors that are structurally diverse (e.g., arylamides and diarylureas, indolylamides, and ketone-derived inhibitors). The p38 inhibitors differ in chemical structure and binding mode, and there are potent and selective inhibitors that have been included in clinical trials. However, only a few lead compounds (BIRB796, SCIO469, and VX702) have progressed to phase II trials and BIRB796 has been withdrawn. One of the main causes for stopping development of these inhibitors is related to an undesirable safety profile, with hepatic and neurological adverse effects and other safety concerns such as infection, skin, and renal disorders. It has not been determined whether the secondary effects are associated directly with p38 inhibition or to other effects of the drugs, but evidence showing different toxicity profiles for each structural class of inhibitors suggests that selectivity plays a role in the unsuccessful use of p38 inhibitors in the clinical setting. In fact, certain p38 inhibitors such as SB203580, SB202190, VX745, and BIRB796, which were thought to be highly selective, have been shown to affect other kinases and certain cross-reactivity with other cellular proteins might also occur [31].

***Acute Coronary Syndromes (ACS)*** It is well known that two kinds of stress-activated MAPKs (JNK and p38) are activated by ischemia/reperfusion (I/R), and there is some indication that inhibition of either might prove helpful for treating ACS. However, it has been difficult to validate whether activation of these kinases is beneficial or detrimental [4]. Some p38 inhibitors, such as SB203580 and SB242710, have shown to reduce I/R-induced apoptosis and preserve cardiac function in a rabbit heart model. Since the heart in this model is perfused and therefore there are no leukocytes, the findings suggest that p38 inhibition has additional reperfusion directly on the myocardium aside from its known effects on leukocyte recruitment and activation. It is thought that this leukocyte-independent protective effect of p38 inhibition on the heart could be associated to a decrease of I/R-induced production of cytotoxic cytokines and blocking of p38-dependent proapoptotic pathways in cardiomyocytes [4]. A p38 inhibitor that can be used in vivo models (SB239063) has beneficial effects in the intact rat model of I/R injury. The antagonist directly protects cardiomyocyte survival and produces a dramatic reduction of the inflammatory response in the heart, as evidenced by decreased upregulation of P-selectin and intercellular adhesion molecules and lower neutrophil accumulation within the ischemic zone. Also, some p38 inhibitors help preserve mechanical function of cold-stored hearts before transplantation, which may be related to augmented contractility due to enhanced calcium responsiveness of myofilaments [4].

Blocking the release of inflammatory cytokines and chemokines could be a promising approach against ACS and might slow the development and progression of atherosclerotic plaque. Indeed, VX702, a p38 inhibitor, is currently being tested in a phase II clinical trial with patients that have ACS with unstable angina [4, 20]. Preliminary safety data showed no clinically significant adverse events, such as bleeding and arrhythmias. Additionally, VX-702 was reported to reduce serum levels of C-reactive protein in patients with ACS undergoing percutaneous coronary intervention (PCI), and these remained significantly lower up to 4 weeks after a 5-day dosing period [8, 20].

Evidence suggests that p38a may play a key role in the pathogenesis of cardiac dysfunction, and its inhibition may have cardioprotective effects associated with attenuation of the inflammatory response and the functional deterioration present in acute myocardial infarction. In a rat model of L-NAME/ANG-II-induced myocardial injury, inhibition of p38a with the selective oral antagonist, SD-282, has been shown to be related to improvement of cardiac function (i.e., increasing stroke volume, cardiac output, ejection fraction and stroke work, and decreasing arterial elastance), reduction of inflammatory cell infiltration (i.e., macrophages), and abolishment of myocyte apoptosis [32]. On the other hand, p38 and ERK1/2 activation may play a cardioprotective role. There are data suggesting that cannabinoids can protect against ischemia in animal models, and the use of a selective CB2 receptor agonist JWH133 appears to reduce infarct size. Studies with pharmacological inhibitors suggest that p38 ERK1/2 and PKC contribute to the protective effect of cannabinoids.

Furthermore, JWH133 in healthy hearts seems to increase p38 phosphorylation and activity, and the cannabinoid receptor 1 (CB1) receptor agonist arachidonyl-2-chloroethylamide (ACEA) appears to increase ERK1/2 phosphorylation without any change in activity. During ischemia, both agonists increased p38 activity, and arachidonyl-2-chloroethylamide (ACEA) favored ERK1/2 phosphorylation and activity during reperfusion [33].

***Heart Failure*** Inhibition of p38 by SB203580 may enhance cell contractility in a dose-dependent manner and reduce cardiac hypertrophy [23]. It is thought that p38 is involved in mediating the action of pro-inflammatory cytokines. In fact, the p38 inhibitor RWJ-67657 appears to reduce remodeling and fibrosis in rats with myocardial infarction secondary to permanent coronary ligation. In fact, some of these compounds seem to be potent antagonists of the tumor necrosis factor (TNF) and other pro-inflammatory cytokines in humans. Clinical trials are currently underway for non-cardiovascular indications (e.g., rheumatoid arthritis and Crohn's disease), and cardiovascular disease (e.g., atherosclerosis) [21].

It could be possible that a broad anticytokine therapy in heart failure using p38 inhibitors could be promising; however, the RENEWAL (Randomized Etanercept Worldwide Evaluation) and ATTACH (Anti-TNF Therapy Against Congestive Heart Failure) trials, targeting TNF-α in heart failure with a monoclonal antibody or a soluble receptor, had negative results and raised concerns [4].

It remains to be determined how the knowledge of MAPK signaling in the heart could be used for treating human pathology since pharmacological ERK1/2 inhibition could decrease the beneficial aspects associated with compensated hypertrophy, whereas p38 or JNK inhibition may lead to a maladaptive hypertrophic response in the long term [22].

***Stroke*** Antagonism of several MAPKs, such as extracellular signal-regulated kinases (ERKs), JNKs, and p38, has been shown to be beneficial in animal models of stroke [4]. It appears that the MEK (mitogen-activated protein kinase kinase)-ERK pathway is turned on during focal cerebral ischemia and participates in the induction of damage in mice since treatment with the MEK1-specific inhibitor PD98059 before ischemia reduces focal infarct volume up to 72 h after transient occlusion of the midcerebral artery in a dose-dependent manner and with attenuation of neurological deficit, thus conferring a potent neuroprotective effect. Furthermore, PD98059 does not seem to alter respiratory and cardiovascular parameters nor produce hypothermia in this setting. On the other hand, in this model of focal cerebral ischemia, p38 and c-Jun phosphorylation do not appear to be increased, and, thus, no protection against brain injury is apparent with the p38 and JNKs inhibitor SB203580 [34].

In rat models of focal ischemic stroke there seems to be p38 activation in the brain, and oral or intravenous administration of the p38 antagonist SB239063, which has high selectivity and improved cellular and in vivo activity profiles, has been shown to reduce infarct size and neurological deficit. In addition to reducing p38 activity, SB239063 also seems to decrease stroke-induced expression of cytokines associated with brain injury [e.g., interleukin-1β (IL-1β) and TNF-α] [35].

Even though ERKs have generally been thought to be antiapoptotic in most settings, including I/R injury in the heart, neuroprotection in vivo has been achieved by direct injection into the cerebral ventricles of a MEK1/2 inhibitor (PD98059), which prevents ERK activation. In addition, studies showed that intravenous administration of another MEK1/2 inhibitor (U0126) was also protective against forebrain and focal cerebral ischemia. It has been suggested that in the brain, the mechanism of protection by ERK inhibition may involve prevention of excitotoxicity (i.e., neuronal death caused by release of excitatory amino acids that activate glutamate receptors), which plays a critical role in I/R injury. However, both inhibitors, PD98059 and U0126, also block MEK5, the kinase that activates ERK5, and it is not known whether this is relevant for the described effect [4]. In a phase I dose-ranging trial in cancer patients, another MEK1/2 inhibitor (PD184352) has been well tolerated with only fatigue, rash, and diarrhea when administered orally twice daily, for periods of 3 weeks and repeating every 4 weeks [4].

Some other possible targets for neuroprotection include the inactivation of JNK3 in the central nervous system via gene deletion in knockout mice, and inhibition of p38 by SB239063 is also protective since it reduced stroke-induced expression of TNF-α and IL-1β, which seem to enhance neuronal loss after I/R [4]. Another potent p38 inhibitor (SCIO 323) entered phase I clinical trials and showed potential therapeutic value against cerebral ischemia and diabetes mellitus [8].

### 3.2 G-Protein-Coupled Receptor Kinases (GRKs)

β-ARK1 inhibition may be a therapeutic option in human heart failure. Inhibition of cardiac β-ARK1 (beta-adrenergic receptor kinase 1) activity with a Gβγ sequestering peptide (β-ARKct) in transgenic models of heart failure appears to restore the ventricular contractile response to β-adrenergic stimulation. In fact, β-ARKct has been described to prolong survival

and improve cardiac function in a murine model of severe cardiomyopathy due to calsequestrin overexpression. Expression of β-ARKct in failing human cardiomyocytes seems to improve β-adrenergic responsiveness and contractile function. There is data in transgenic mice with pressure overload and varying degrees of cardiac-specific expression of β-ARKct peptide that suggest a correlation between the level of β-ARK1 inhibition and the degree of heart failure. Moreover, there seems to be a positive linear relationship between β-ARKct expression and fractional shortening (i.e., animals with high β-ARKct expression show less cardiac deterioration, preserved adenylyl cyclase activity with isoproterenol stimulation, and normal β-AR density), suggesting that the degree of β-ARK1 inhibition could have relevant therapeutic repercussions. Other signaling proteins that interact with β-ARK1 might be attractive therapeutic targets since there is no pharmacological inhibitor currently available [1].

### 3.3 Phosphatidylinositol 3-Kinase (PI3K) Signaling

Since PI3Kγ has a relevant role in regulating vascular smooth muscle tone, cardiac cell contractility, and inflammatory responses, it is an attractive target for cardioprotective therapies. There is interest in finding novel agents with dual effects on both the mechanical (pressure and contractility) and the inflammatory components of cardiovascular disease. In fact, this would match the expected profile from an ideal PI3Kγ inhibitor, based on data obtained from experimental animal models of cardiac overload and inflammation [5]. There is data suggesting that PI3Kγ expressed in smooth-muscle cells participates in regulating the balance between vasodilation and vasoconstriction, which is mediated by vasoactive GPCR agonists, such as angiotensin (Ang) II. It has been described that Ang-II-induced vasoconstriction in smooth-muscle cells is impaired by nonselective PI3K inhibitors, but only selective antagonism of PI3Kγ inhibits the Ang-II-induced phosphatidil inositol cascade and calcium influx. In fact, transgenic mice deficient in PI3Kγ are resistant to the hypertensive effect of chronic Ang II exposure. Consequently, PI3Kγ inhibition may potentially be useful to treat high blood pressure [5]. Moreover, PI3Kγ in cardiac myocytes regulates contractility without participating in growth control under normal conditions, and the absence of PI3Kγ function favors increased contractility in cardiomyocytes [5].

Recently, intravenous PI3Kγ inhibitors, such as TG100-115 (Targegen), are being evaluated for the treatment of acute myocardial infarction. Preclinical data show that TG100-115 lowers vascular permeability and reduces myocardial infarct development with improved myocardial contractility in animal models. The compound has been described to be selective for PI3K compared to other kinases and has limited selectivity within the class I PI3Ks. Apparently, no PI3Kγ inhibitor has progressed to the clinical setting yet since further research is needed in this area, and the initial patent applications are still very recent. There is a need to identify potent and selective inhibitors with acceptable pharmacokinetic properties that are effective and safe. When developing a new drug for the treatment of a given disease, the right balance must be achieved with reasonable isoform selectivity and potency combined with maximum efficacy and minimal unwanted adverse effects. Since there appears to be interdependence and cooperation between class IA and IB PI3K isoforms in the same cell type, dual inhibition of PI3Kγ and of a class IA PI3K (depending on the cell type, e.g., PI3Kβ in platelet aggregation and PI3Kα in cardiac myocyte function) might be desirable to reach a therapeutically useful effect [5]. Animal studies suggest that targeting PI3K might have similar results to those associated with βARK1 blocking since PI3Kγ interacts directly with βARK1 and, thus impacts cell contractility through β-adrenergic desensitization. Given the individual roles of the different PI3K isoforms, a PI3Kγ-specific inhibitor could attenuate its unwanted effects on calcium handling, β-adrenergic signaling, cardiac contractility, and hypertrophy [1].

The experimental evidence available validates PI3Kγ as a high potential target for the treatment of various cardiovascular disorders, such as thrombosis, atherosclerosis, and cardiac hypertrophy. PI3Kγ is involved in several different processes relevant to human disease but controls only a fraction of these. Thus, even potent and selective PI3Kγ antagonism would be expected to just reduce rather than eliminate any given biochemical event, and this subtle form of inhibition would affect several processes implicated in the multifactorial pathogenesis simultaneously. This would result in a concurrent, multibranched mode of action in different cell types and tissues with a beneficial overall therapeutic effect in a specific disease setting. Based on the restricted expression pattern of PI3Kγ, its limited functional association to a couple of GPCRs, and the benign phenotypes of PI3Kγ knockout and knock-in mice, the initial concerns about safety of selective PI3Kγ inhibitors have largely decreased. However, potential toxicity associated with PI3Kγ antagonists, including interference with innate immunity, blood pressure, or wound healing, cannot be ruled out [5]. It has been suggested that in vitro inhibition of PI3K using wortmannin or LY294002 in cultured cardiac myocytes decreases basal protein synthesis in resting cells and after stimulation

with phenylephrine or insulin. In addition, PI3K inhibition modulates gene expression, apparently through GSK3β [1].

Available PI3K inhibitors, such as wortmannin and LY294002, have been used to define PI3K-mediated signaling, but they have poor selectivity for different isoforms [1]. In fact, wortmannin can also inhibit other PI3K-related enzymes such as mammalian target of rapamycin (mTOR), DNA-dependent protein kinase (DNA-PK), some phosphatidylinositol 4-kinases, myosin light-chain kinase (MLCK), and mitogen-activated protein kinase (MAPK) at high concentrations [36, 37]. Other agents, such as AS-604850 and AS-605240, have been shown in vitro and in vivo to selectively inhibit PI3Kγ enzymatic activity, signaling, and chemotaxis. There is evidence to suggest that oral AS-605240 prevents progression of joint inflammation and damage in mouse models of rheumatoid arthritis as well as glomerulonephritis in murine models of systemic lupus. The efficacy of this inhibitor in cardiovascular disease is not known [1].

### 3.4 Rho-Dependent Serine–Threonine Kinases (ROCKs)

In several animal models and human trials, potentially beneficial effects of ROCK inhibitors in cardiovascular disease related to VSMC hyperconstriction (such as coronary and cerebral vasospasm, pulmonary hypertension, and systemic hypertension) have been identified. In addition, these compounds might also show benefits if used to treat stroke, coronary restenosis, I/R injury, heart failure, myocardial hypertrophy, cardiac allograft vasculopathy, and vein graft disease [9]. Fasudil has shown that ROCK mediates increased vascular resistance and impaired vasodilation in patients with heart failure patients or hypercholesterolemia. In fact, ROCK may participate in hemodynamic abnormalities seen in metabolic syndrome and obesity [7]. However, further studies are needed to prove the potential usefulness of oral ROCK inhibitors for the treatment of myocardial infarct, unstable angina, pulmonary hypertension, hypertensive vascular disease, and cardiac hypertrophy in humans [9].

***Current Status of the Development of Selective ROCK Inhibitors (Table 3)*** [9] Fasudil is the only ROCK inhibitor available for clinical use and is accessible only in Japan to treat cerebral vasospasm after subarachnoid hemorrhage. Clinical trials to test its antianginal effects in patients with stable angina have demonstrated that long-term oral treatment with this drug is safe and effective, improving the ST-segment depression in patients with stable angina; the drug was well tolerated and did not affect heart rate or blood pressure [9]. Fasudil selectively competes with ATP for binding to ROCK, and its

**TABLE 3 ROCK Inhibitors under Current Development to Treat Cardiovascular Disease and Other Pathologies**

| Compound | Stage of Testing | Indication |
|---|---|---|
| Fasudil (Asahi Kasei Pharma—Japan) | Launched | Cerebral vasospasm |
| | Registered | Acute cerebral ischemia |
| | Phase II | Angina |

major active metabolite after oral administration, hydroxyfasudil, has a more selective inhibitory effect on this kinase than the parent drug. However, both compounds exert nonspecific inhibitory effects on other serine/threonine kinases such as PKA and PKC [9]. At micromolar concentrations, fasudil inhibits several protein kinases, including ROCKs, but it is unclear whether its clinical efficacy results from inhibition of this or other protein kinases, or whether it is due to a non-kinase effect [6]. Certain fasudil analogs have proven to be highly specific inhibitors of ROCK, and compounds with a better ROCK2 inhibitory profile have been developed. These antagonists have been used to reduce intraocular pressure in rabbit ocular hypertensive models, which indicates that they might be useful for glaucoma, in addition to other ROCK-related diseases. Recently, GSK269962A and SB772077B have been described as members of a novel class of compounds that have similar inhibitory effects on ROCK1 and ROCK2 as Y27632 or fasudil but with higher potency [9]. Furthermore, an orally bioavailable, potent, and highly selective ROCK2 inhibitor, SLx2119, has been developed recently [9], but clinical trials are still pending.

***Hypertension*** Selective ROCK inhibitors might potentially be a novel approach to the treatment of hypertension in the future [4]. Several studies in spontaneously hypertensive rats, deoxycorticosterone acetate (DOCA)-salt-treated hypertensive rats, and renal hypertensive rats have shown that specific ROCK inhibitors, such as Y-27632, GSK269962A, and SB772077B, have vasodilator activity and lower systolic blood pressure, not affecting blood pressure in normal rats. However, this specific compound apparently affects contraction of smooth muscle cells outside the vasculature, as well as metastasis and neurite outgrowth; therefore the safety of Y-27632 and related agents remains to be evaluated in clinical trials [4, 9].

Intra-arterial infusion of fasudil enhances the vasodilator responses of forearm circulation in hypertensive patients; in fact, it has been reported to be significantly greater in hypertensive patients than in normal subjects. Thus, Rho-kinase may be involved in the pathogenesis of the increased peripheral vascular resistance in human hypertension [9, 38].

***Coronary Vasospasm and Angina*** ROCKs phosphorylate the myosin-binding subunit of myosin light-chain phosphatase and LIM kinase, which ultimately regulates myosin light-chain phosphorylation and thus vascular smooth-muscle cell contraction. Therefore, ROCK inhibition may regulate the calcium sensitivity of smooth-muscle cells in coronary arteries and thus favor coronary vasodilatation. In fact, it has been shown in a pig model that hydroxyfasudil blocks myosin light-chain phosphorylation and significantly inhibits coronary spasm [4]. Hydroxyfasudil has also a cardioprotective effect on coronary I/R injury in canine coronary microcirculation since it preserves endothelium-dependent vasodilator responses after I/R and decreases MI size for which nitric-oxide-mediated mechanisms may be involved [39, 40].

In vivo evidence shows that directed ROCK inhibition by adenovirus-mediated transfer of dominant negative Rho-kinase (DNRhoK) induces a marked regression of coronary constrictive remodeling and abolishes coronary vasospastic activity in 3 weeks in porcine coronaries chronically exposed to IL-1β [41].

A couple of small clinical trials propose that fasudil lessens myocardial ischemia in subjects with stable or vasospastic angina. It appears that this compound considerably increases the ischemic threshold during exercise in angina patients, with a trend toward increased exercise duration [1]. In one study that evaluated the involvement of ROCK in coronary microvascular dysfunction associated with effort angina, intracoronary administration of fasudil increased the oxygen saturation in coronary sinus vein and ameliorated pacing-induced myocardial ischemia in patients with stable effort angina without significant hemodynamic changes. These results are interpreted as suggestive that the ROCK pathway in the coronary microcirculation is not functional under normal conditions but appears to be upregulated under pathological conditions such as stable effort angina. It is not known whether long-term treatment with fasudil improves prognosis of patients with effort angina [42].

***Cerebral Vasospasm and Stroke*** ROCKs may be considered as a therapeutic target for ischemic stroke since fasudil had a positive impact on cerebral blood flow and infarct size in a murine model with cerebral artery occlusion. The neuroprotective effects have been linked to increases in eNOS expression and activity [1, 9].

***Pulmonary Hypertension*** In a rat model of monocrotaline-induced pulmonary hypertension, overall survival has been reported to improve, and the development of severe pulmonary hypertension, right-ventricular hypertrophy, and pulmonary vascular lesions to be decreased after long-term inhibition of Rho-kinase with fasudil administered orally. The beneficial effects appear to be present both when the drug is started concomitantly with monocrotaline and also when started after development of pulmonary hypertension. Apparently, fasudil's related improvement in this model is linked to suppression of VSMC proliferation and macrophage infiltration, enhanced VSMC apoptosis, and amelioration of endothelial dysfunction and VSMC contraction. However, it is important to

**TABLE 4 Cardiovascular Toxicity of Tyrosine Kinase Targeting Drugs Used in Oncology[a]**

| Agent | Molecular Target | Oncologic Target | Cardiovascular Toxicity[b] | Other Toxicity |
|---|---|---|---|---|
| Trastuzumab (Herceptin) | ERBB2 | Breast cancer | Known or likely cardiotoxicity | Infusion reactions, neutropenia |
| Imatinib (Gleevec) | ABL1/2 PDGFRα/β KIT | CML, Ph+ B-ALL, CMML, CEL, GIST | Known or likely cardiotoxicity Edema | Nausea, myelosuppression, immunosuppression |
| Dasatinib (Sprycel) | ABL1/2, PDGFRα/β, KIT, Src family | CML | Known or likely cardiotoxicity Edema, pericardial effusion, QT prolongation, hemorrhage | Myelosuppression, pleural effusion, panniculitis |
| Nilotibib (Tasigna) | ABL1/2, PDGFRα/β, KIT | CML | Known or likely cardiotoxicity QT prolongation | Myelosuppression, hyperbilirubinemia, rash |
| Sunitinib (Sutent) | VEGFR1–3, KIT, PDGFRα/ β, RET, CSF1R, FLT3 | Renal cell carcinoma, GIST | Known or likely cardiotoxicity Hemorrhage, hypertension | Adrenal dysfunction, hypothyroidism |
| Sorafenib (Nexavar) | VEGFR2, PDGFRβ, KIT, FLT3, RAF1, BRAF | Renal cell carcinoma, melanoma | Known or likely cardiotoxicity Acute coronary syndromes Hemorrhage, hypertension | Skin rash |
| Bevacizumab (Avastin) | VEGFR | Colorectal cancer, NSCLC | Known or likely cardiotoxicity Arterial thromboembolism Hemorrhage, hypertension | Gastrointestinal perforation, poor wound healing, neutropenia |
| Lapatinib (Tykerb) | EGFR | Breast cancer | Low cardiotoxicity | Skin rash, diarrhea |
| Gefitinib (Iressa) | EGFR | NSCLC | Low cardiotoxicity | Skin rash, diarrhea, nausea, interstitial lung disease |
| Erlotinib (Tarceva) | EGFR | NSCLC, pancreatic cancer | Low cardiotoxicity | Skin rash, diarrhea, nausea, interstitial lung disease |
| Cetuximab (Erbitux) | EGFR | Colorectal cancer, squamous cell carcinoma of head/neck | Low cardiotoxicity | Skin rash, infusion reactions, interstitial lung disease, hypomagnesemia |
| Panitumumab | EGFR | Colorectal cancer | Low cardiotoxicity | Skin rash |

[a]ERBB2, receptor tyrosine kinase member of the EGFR family; EGFR, epidermal growth factor receptor; ABL, Abelson tyrosine kinase; PDGFR, platelet-derived growth factor receptor; KIT, receptor for stem cell factor; CML, chronic myeloid leukemia; Ph+, Philadelphia chromosome positive; B-ALL, B-cell acute lymphoblastic leukemia; CMML, chronic myelomonocytic leukemia; CEL, chronic eosinophilic leukemia; GIST, gastrointestinal stromal tumor; QT, QT interval on electrocardiogram; VEGFR, vascular endothelial growth factor receptor; RET, rearranged during transfection; CSF1R, colony-stimulating factor 1 receptor;
FLT3, FMS-related tyrosine kinase 3; NSCLC, non-small-cell lung cancer,
[b]Rate of cardiotoxicity is known only for trastuzumab and lapatinib.

mention that some animals in the fasudil groups died because of right-ventricular failure, thus suggesting that treatment with this compound was not effective in all animals [43].

In a pulmonary hypertension model induced by hypoxia using wild-type and eNOS-deficient mice, long-term inhibition of Rho-kinase with fasudil improved the hypertension and right-ventricular hypertrophy in wild-type mice and to a lesser extent in eNOS knockout mice. However, the therapeutic effects of fasudil after the development of hypoxia-induced pulmonary hypertension need to be evaluated [44].

Pulmonary vascular resistance in patients with pulmonary hypertension is significantly reduced by intravenous infusion of fasudil; in fact, the intravenous administration of fasudil appears to have an acute pulmonary vasodilator effect. There are current plans to perform clinical trials with long-term oral treatment with fasudil in patients with pulmonary hypertension in Japan [9, 18].

***Heart Failure*** It has been suggested that activation of Rho-kinase is involved in the increased peripheral vascular resistance seen in patients with congestive heart failure (CHF) [9, 45]. Furthermore, fasudil-mediated vasodilation correlates to plasma brain natriuretic peptide (BNP) levels, suggesting an activation of the Rho/Rhokinase pathway directly related to the severity of CHF [45].

***Atherosclerosis*** Selective ROCK2 inhibition with SLx2119 seems to attenuate arterial plaque formation in apolipoprotein-E-deficient mice, indicating that this selective antagonism could limit atherosclerosis without the unwanted hemodynamic side effects seen with nonselective ROCK inhibitors [9]. It has been established that long-term treatment with fasudil blocks macrophage accumulation in the adventitia and decreased migration into the media with subsequent inhibition of coronary lesion formation in a porcine model of coronary arteriosclerosis. In this experimental model, the atherosclerotic lesions where established through monocyte chemoattractant protein-1 and oxidized low-density lipoprotein. Furthermore, this drug suppressed in-stent neointimal formation in porcine coronary arteries through various mechanisms, including reduced vascular inflammation, enhanced apoptosis, and decreased collagen deposition. Thus, long-term ROCK inhibition induces a considerable regression of coronary remodeling and vasospasm in a porcine model with adventitial inflammation [9].

***Metabolic Syndrome*** ROCKs may interfere with insulin signaling by favoring insulin receptor substrate-1 (IRS-1) phosphorylation in cultured VSMC. ROCK activation has been found in skeletal muscle and aortic tissue of Zucker obese rats. In fact, long-term ROCK inhibition appears to decrease blood pressure, correct glucose and lipid metabolism, recover insulin signaling, and improve endothelial dysfunction [1].

### 3.5 Protein Kinase C (PKC) and Protein Kinase A (PKA)

In a clinical trial, the PKCβ inhibitor LY333531 has been shown to be safe and effective in treating diabetes-induced retinal hemodynamic abnormalities [1].

There is evidence that shows cAMP accumulation and PKA activation with increased opening of L-type calcium channels in myocardial ischemia. This is associated with reperfusion dysrhythmias and necrosis (i.e., reperfusion injury). In fact, the use of H89 in isolated rat heart appears to have a cardioprotective effect associated with PKA inhibition, improved contractile recovery, and reduction of infarct size, both when given as pretreatment or preconditioning [10].

Since heart failure is associated with activation of the β-adrenergic signal transduction pathway and the beneficial action of β-adrenergic blockade in this setting, PKA inhibition may be an additional target in the treatment. However, it appears that H89 is used only in preclinical research, and it remains to be established whether inhibition of PKA could have additional advantages above conventional β-adrenergic blockade [10]. PKCβ may be an attractive therapeutic target in patients with heart failure since signaling of many circulating neurohormones (e.g., α-adrenergic system, endothelin, and angiotensin II) is associated with this enzyme. The PKCβ inhibitor ruboxistaurin seems to exert antifibrotic effects after experimental myocardial infarction [21].

Other PKA antagonists have been developed, such as the cAMP analog Rp-cAMPS, whose effect is strongly dependent on kinase concentration (i.e., the higher the kinase concentration, the more efficient), and the protein kinase inhibitor (PKI) peptide, which is an endogenous peptide that modulates PKA function. In fact, Rp-cAMPS and synthetic PKI analogs seem to be more specific inhibitors of PKA than H89 [10].

### 3.6 Calcium/Calmodulin-Dependent Protein Kinase II (CaMKII)

It is known that structural heart disease is associated with electrical instability and arrhythmias, myocardial dysfunction, myocardial hypertrophy, and chamber dilation. Targeted CaMKII inhibition could improve some of these fundamental changes since there is evidence of altered CaMKII expression or activity in structural heart disease and some studies show that introducing an excess or constitutively active mutant leads to the disease in a previously normal tissue, whereas knocking out the protein or inhibiting its activity could be protective [11]. Genetic inhibition of CaMKII confers resistance to development of cardiac hypertrophy associated with excessive and sustained catecholamine stimulation. In contrast, some results suggest that CaMKII inhibition restores myocardial function in calcineurin cardiomyopathy with a minimum effect on reducing hypertrophy. Thus, CaMKII overactivity may have deleterious effects on cardiomyocyte function independent of cardiac hypertrophy. In vivo studies suggest that transgenic mice with CaMKII inhibition are resistant to apoptosis related to ischemia and high-dose isoproterenol. Furthermore, CaMKII inhibition seems to protect from developing apoptosis in phospholamban knockout mice. Therefore, it is thought that CaMKII antagonism can modulate cell death associated with ischemia and catecholamine toxicity [24].

Protein kinases involved in calcium-signaling pathways, such as Rho kinases and PKC, represent a poten-

tial therapeutic target in cardiovascular disease. ROCKs and PKC are upstream modulators of calcium homeostasis, while CaMKII is a downstream target. CaMKII is activated by β-adrenergic stimulation, and CaMKII antagonism appears to be beneficial without affecting the normal sympathetic responsiveness as with beta-blockers. It has been described that CaMKII antagonism in cardiac myocytes using the small peptide inhibitor of CaMKII AC3-I or the inhibitor KN-93 reduces cardiac hypertrophy and contractile dysfunction secondary to MI and chronic β-adrenergic stimulation. Nevertheless, AC3-I transgenic mice seem to have normal basal function and preserved acute β-adrenergic response. Furthermore, genetic inhibition provides evidence that CaMKII activity is needed for normal AV nodal conduction since antagonism slows conduction through this node, which suggests a potential therapeutic use of CaMKII [1].

It is well known that the β-adrenergic system is a prominent regulator of cardiac function, and blocking it is nowadays the major therapy for treating patients with structural heart disease and myocardial dysfunction. The traditional β-adrenergic signaling pathway involves activation of PKA, which targets many of the same proteins in the calcium cycle as CaMKII, leading to increases in calcium mobilization. In fact, there is evidence that CaMKII is an important downstream effector of the β-adrenergic receptor signaling cascade. Transgenic overexpression of a CaMKII inhibitory peptide (AC3I) ameliorates the deleterious impact of MI on left-ventricular function since the CaMKII block seems to prevent maladaptive remodeling associated with excessive β-adrenergic stimulation and induces balanced changes in excitation–contraction coupling needed for cardiac function [11, 46]. In addition, chronic inhibition of CaMKII in AC3I mice and acute inhibition with KN93 protects from cardiomyopathic responses seen with chronic β-adrenergic stimulation. It has been shown that CaMKII activity directly contributes to the loss of calcium homeostasis in two cardiac disease models associated with β-adrenergic activation [11]. There is data showing that CaMKII antagonism protects against apoptosis in vivo after myocardial infarction or excessive stimulation with isoproterenol. In fact, transgenic mice that express CaMK inhibitory peptide present a cardioprotective effect after MI and chronic β-adrenergic stimulation [11]. It appears that CaMKII is an attractive drug target in structural heart disease and arrhythmias. However, this multifunctional kinase has many known roles in cell functioning (e.g., gene regulation and molecular memory), and its complete block could be associated with unwanted adverse effects. Thus, it could be attractive to selectively target CaMKII substrates that are critical for calcium cycling [11]. The current knowledge of the structure of the regulatory and catalytic domains of CaMKII could facilitate the development of specific inhibitory agents. For example, inhibitors of CaMKII, such as KN62 and KN93, bind to the calcium/CaM domain and block CaMKII activation in cardiac myocytes. However, the results obtained with these drugs need to be interpreted with care because these drugs have effects on multiple ion channels, and more selective CaMKII inhibitors are needed [11].

### 3.7 Mammalian Target of Rapamycin (mTOR)

Rapamycin inhibits proliferation and migration of rodent and human VSMCs in vitro and porcine VSMCs in vivo by blocking cell cycle progression at the G1/S transition. In fact, a rapamycin-induced effect on VSMC appears to be related with a marked reduction in cyclin-dependent kinase (CDK) activity and retinoblastoma protein phosphorylation [47]. The use of stents covered with rapamycin/sirolimus, and thus local mTOR inhibition, prevents growth and proliferation of VSMC and coronary restenosis [1, 4]. The implantation of rapamycin-coated stents in lesions appears to be safe and effective in inhibiting neointimal formation. However, rapamycin seems to increase tissue factor expression associated with potential subacute and late stent thrombosis. Nevertheless, other studies suggest that regardless of enhanced tissue factor expression secondary to mTOR inhibition, there is no increased tissue factor activity.

It has been suggested that rapamycin has a preconditioning-like effect against myocardial infarction. In fact, rapamycin and mTOR blockage appears to have a protective effect in I/R injury since pretreatment of murine hearts reduced infarct size and decreased cardiac myocyte cell death [1].

### 3.8 Glycogen Synthase Kinase-3β (GSK-3β)

Even when GSK was identified in the 1970s as a kinase that blocks glycogen synthesis, it was not considered a potential drug target until the 1990s, when its function in insulin signal transduction was elucidated and its probable value in Alzheimer's disease emerged. The use of several potent GSK3 inhibitors in cell-based assays and animal models of type II diabetes suggest they are effective in lowering blood glucose levels, and thus they may have therapeutic potential for the management of diabetes [12]. It has been proposed that GSK3 inhibitors might be advantageous for treating diabetes because (1) insulin favors activation of glycogen synthase by restraining GSK3 activity, (2) there is elevated GSK3 expression in diabetic muscle, and (3) GSK3 appears to

attenuate insulin signaling by phosphorylating and downregulating IRS-1 in overexpression studies. Consequently, GSK3 antagonists could mimic insulin's ability to favor glucose conversion to glycogen, and thus overcome the insulin resistance associated with inhibition of the pathway at the insulin receptor/IRS level. In fact, the use of lithium, a relatively specifically in vitro GSK3 inhibitor, appears to activate glycogen synthase and to stimulate glycogen synthesis in muscle. Furthermore, in the late 1990s, a class of maleimides that blocked GSK3 more potently than lithium was identified, and these compounds (SB 216763 and SB 415286) were shown to activate glycogen synthase and speed up glucose conversion to glycogen in human liver cells. In addition, there is data reporting that other compounds in this class normalize blood glucose levels in vivo. On the other hand, these new compounds and lithium appear to share insulin's ability to suppress phosphoenolpyruvate carboxykinase and glucose-6-phosphatase transcription, the key rate-limiting enzymes of gluconeogenesis. These observations suggest that GSK3 antagonists might suppress glucose production by the liver and enhance its conversion into glycogen. However, SB 216763 and SB 415286 inhibit other protein kinases (e.g., cyclin-dependent protein kinases or CDKs) and lithium affects other distinct protein kinases and also blocks nonkinase targets (e.g., inositol monophosphatase and histone deacetylase). Thus, it is important to show that structurally diverse GSK3 inhibitors act similarly, before concluding that these effects are actually mediated via the inhibition of GSK3. Other compounds are being studied. For example, azakenpaullone seems to have greater selectivity for GSK3 than CDK1 and CDK5, and thienyl and phenyl α-halomethyl ketones are said to inhibit GSK3 without inhibiting PKA; but further information is needed regarding its selectivity against a large panel of other protein kinases. Although it has been established that a concentration in the micromolar range is needed for inhibition in vitro, these compounds and lithium are noncompetitive inhibitors, while SB 216763 and SB 415286 are ATP competitive. There are advances in the development of more potent and specific GSK3 antagonists that do not affect CDKs, such as CHIR 99021, AR-A014418, and bis-7-azaindolylmaleimides. A couple of studies report that CHIR 99021 and closely related compounds (CHIR 98023 and CHIR 98014) activate glycogen synthase and stimulate glycogen deposition in the liver. Furthermore, these drugs appear to be effective in lowering glucose and insulin concentrations in oral glucose tolerance tests in Zucker Diabetic Fatty (ZDF) rats, which reflects improved sensitivity to insulin. In studies lasting up to 24 h, CHIR 99021 seems to lower the fasting blood glucose level, probably associated to inhibition of gluconeogenesis. In fact, these compounds have been reported to be effective in three different rodent models of type II diabetes. In order to determine the real therapeutic value of GSK inhibitors in diabetes, even when these compounds appear to effectively lower blood glucose in rodent models of type II diabetes, there is still a need to extend these studies to non-leptin-deficient models of type II diabetes and rodent models of type I diabetes, and further studies are required to evaluate these drugs in humans [12]. It has been noted that GSK3 inhibitors might mimic the Wnt signaling pathway and therefore be potentially oncogenic. In fact, there is evidence that shows SB 216763, SB 415286, and lithium increase β-catenin levels in transformed cell lines. Furthermore, since GSK3 phosphorylates the transcription factors c-jun and c-myc, the inhibition of GSK3 could promote dephosphorylation of proto-oncogenes and thus lead to their activation. However, lithium has been used to treat bipolar disorder for many years, and long-term use does not seem to be associated with increased risk of developing cancer. Furthermore, infusion of CHIR99021 for up to 20 h in ZDF rats was not associated with an increase of β-catenin or cyclin D1 in brain, liver, lung, colon, or adipose tissue. Therefore, it is thought that GSK3 inhibition by itself might not be enough to elevate the levels of β-catenin in normal tissues, as it might only occur in transformed cell lines. Regardless of these assumptions, long-term treatment of cells and animals with GSK3 antagonists are required to fully evaluate this, since these compounds would need to be administered for many years to treat chronic disease states such as diabetes [12].

### 3.9 5′-AMP-Activated Protein Kinase (AMPK)

Another approach to target protein kinase activity is to identify compounds that activate rather than inhibit the enzyme, especially for protein kinases that are beneficially activated by allosteric mechanisms [4]. AMPK activation elevates fatty acid oxidation because it inhibits ACC, the rate-limiting enzyme in fatty acid synthesis that inhibits the catalytic process. In addition, AMPK activation seems to favor lower levels of hepatic sterol response element binding protein 1 and consequently decreases lipogenic gene expression; therefore, serum triglycerides could be lowered by therapeutic activators of AMPK. It has also been shown that AMPK inhibits HMG-CoA reductase, the rate-limiting enzyme in cholesterol biosynthesis, thus blocking cholesterol production and making therapeutic AMPK activators attractive pharmaceutical targets. Furthermore, it seems that AMPK is activated during exercise and is linked to favoring glucose uptake by skeletal muscle in an insulin-independent manner. In fact, there is data showing that AMPK activation with 5-aminoimidazole-4-carboxamide-1-β-D-ribofuranoside (AICAR) triggers

a phenomenon [4]. Moreover, the antidiabetic drug metformin appears to exert its effects in part by activating AMPK [4, 48]. Consequently, activators of AMPK may improve glucose intolerance. In fact in animal models AMPK activation is needed to achieve the inhibitory effect exerted by metformin on glucose production by hepatocytes, and stimulation of glucose uptake in skeletal muscle [49]. Alternative ways of modulating AMPK could be useful for the treatment of metabolic disorders [4, 49].

There is evidence that suggests polyphenols, such as resveratrol (found in red wine), apigenin, and S17834 increase AMPK and its downstream target ACC in hepatocytes, and they appear to be more potent than metformin. These compounds and genetic overexpression of AMPK also seem to prevent lipid accumulation related to high glucose exposure [25].

AMPK stimulation in type I diabetic low-density lipoprotein (LDL) receptor-deficient mice (DMLDLR–/–) with S17834 has been described to revert the decrease in AMPK and ACC activation and to prevent lipid accumulation in the liver associated with hyperlipidemia and aortic lesion development [25].

There has been speculation on the multiple advantages and disadvantages of pharmacological AMPK manipulation for treatment of cardiovascular disease. However, some experts say that currently there is no sufficient understanding of the role of AMPK in cardiac health and disease to direct pharmacological treatment for patients. It is recognized that AMPK may eventually be considered as a major regulator of muscle and heart glycogen metabolism, but the current knowledge is based on studies with constitutive mutations, which may not reflect normal cardiac physiology, and further research is required to understand AMPK's contribution to normal glycogen metabolism [14].

### 3.10 Other Protein Kinases

There is evidence that links mutations of WNK (with no lysine family of kinases) with pseudohypoaldosteronism type II, a rare hereditary form of hypertension. In fact, less severe mutations and/or polymorphisms of WNK may play a role in hypertension since there is evidence in the Framingham Heart Study that the *WNK4* gene lies close to a locus showing the strongest linkage to blood pressure variation. Thus WNK could be a potential target in hypertensive patients [4].

The p90 ribosomal S6 kinase (RSK) has been reported to regulate cardiac sodium/hydrogen exchanger isoform 1 (NHE1) activity and thus may be involved in the mediation of myocardial ischemia and I/R injury in the heart. In fact, cardiac-specific overexpression of dominant negative RSK in transgenic mice (DN-RSK-TG) appears to be associated with normal basal cardiac function and morphology, and DN-RSK-TG hearts seem to have reduced myocardial infarction after temporary left coronary artery occlusion. Furthermore, myocyte apoptosis is also shown to be reduced after I/R in DN-RSK compared with nontransgenic littermate controls. There is data that shows these effects to be related to inhibition of NHE1 activity by RSK blockade during I/R. However, large clinical trials to evaluate the NHE1 inhibitors cariporide and eniporide (GUARDIAN trial [Guard during ischemia against necrosis trial] and ESCAMI trial [evaluation of the safety and cardioprotective effects of eniporide in acute myocardial infarction]) in patients with myocardial infarction, show no reduction in mortality, which may be related to the fact that these antagonists block homeostatic functions of NHE1. Thus, targeted inhibition of RSK and reduction of NHE1 activity may be useful to treat cardiac I/R injury [50].

There are some studies that suggest that imatinib inhibits receptor tyrosine kinase signaling and, therefore, might be effective for the treatment of heart failure because it inhibits TGF-β and connective tissue growth factor signaling, which are activated in the ventricular remodeling process. However, it has been shown that imatinib may cause cardiomyopathy through inhibition of c-ABL [21].

## 4 OBSTACLES AND OPPORTUNITIES IN THE CLINICAL DEVELOPMENT OF TARGETED THERAPEUTICS

A critical concern in drug development is the identification of appropriate targets for therapeutic intervention. Since deregulation of a specific protein kinase can be an irrelevant consequence of the disease rather than a key contributing factor to the pathology, when this kinase is being considered as a potential target, it is not enough justification to know whether it is activated or inhibited in a specific disease state. Further evidence, such as clear genetic or physiological data is required that implicates a protein kinase as an attractive target [4]. Once a kinase is validated as a target for drug development, it is crucial to identify a series of promising compounds to be tested. In order to make the identification process efficient, high-throughput screening is needed. Based on the actual crystal structure of the kinase (structure-based library design) or on the structure of compounds already known to bind to the target (ligand-based library design), the virtual screening or molecular modeling turns out to be more proficient [4]. Computer-aided drug design can be an extremely valuable guide to choose the most promising compound since the structure–activity relationship of any candidate drug can be correlated with specific molecular interactions of

the compound with the kinase active site, and in this way the structure of the inhibitor can be optimized. When structure data do not exist for a specific kinase, knowledge of the structure of another member of the family can often be used to create binding models from which optimized compounds can be synthesized. However, it is possible that a compound with apparently high activity and specificity in vitro may display markedly different and even nonspecific activity in vivo [4]. Therefore, it is critical to test the promising drug candidates for safety and efficacy in relevant experimental animal models of cardiovascular disease and, furthermore, test the compounds in well designed clinical trials that will facilitate evidence-based decisions. The ultimate validation can only be reached when a compound shows efficacy and safety in advanced human clinical trials, and the new inhibitors need to have adequate potency, selectivity, and pharmacokinetic profile (absorption, distribution, metabolism, elimination, and toxicity) [5].

### 4.1 Biological Barriers for Drug Delivery

Crystallographic data reveals that kinases have a sufficient degree of uniqueness, which allows developing specific inhibitors. However, antagonism of kinase activity in a diseased tissue could also inhibit desired activity of the same kinase in other tissues, which could be overcome by localized drug delivery [1]. The specific function of a kinase inhibitor needs to be evaluated with caution since there might be nonspecific actions of some compounds at certain concentrations. The drug's cellular uptake, its half-life, diffusion rate, and/or multiple intracellular receptors are also important determinants of the final effect seen in experimental disease models and the clinical setting [3].

The ATP binding site has been more aggressively targeted for drug development than the protein substrate binding site, the interference with anchoring proteins to which kinases bind for proper cellular localization, or with the signaling proteins they recruit to mediate some of their effects. Directing development to the ATP binding site presents certain challenges since all protein kinases bind ATP and have a homologous protein fold, where ATP binds between the small and large lobe of the kinase catalytic domain. Distinct features at these sites have allowed the development of more selective ATP-based inhibitors [2]. However, other intracellular enzymes and proteins bind ATP or other nucleotides and may generate the problem of specificity. Furthermore, a successful antagonist drug needs to have a binding affinity many times higher than ATP since the competitive inhibition of ATP binding happens against millimolar levels of intracellular ATP. The ATP binding pocket of active kinases is homologous while its conformation is distorted and, therefore, more diverse in the autoinhibited state of the kinase. Since some kinases require phosphorylation by other kinases to become active, inhibitors that bind the inactive form could block phosphorylation and activation of the kinase by its protein kinase [2].

### 4.2 Protein Kinase-Modulating Compounds—Assessing and Managing Potential Toxicity

Toxicity remains a major concern because many of these kinases not only play roles in the pathogenesis of disease but also function in pathways that regulate basic cellular processes [4]. Clinical oncological trials have shed some light regarding toxic side effects, but it is important to remember that these studies are designed to identify or use the maximum tolerated dose, which may be considerably higher than the doses needed to treat cardiovascular diseases. Furthermore, the use of combination therapy to target two or more kinases on the same or different pathways may allow the administration of lower and less toxic doses [4].

The first report of cardiac toxicity of a targeted agent was for trastuzumab, cases of CHF have been described after treatment with imatinib, and undesirable cardiac effects are referred to in the prescribing information for dasatinib, sunitinib, sorafenib, and bevacizumab. However, cardiotoxicity seems not to be a tyrosine kinase inhibitor class effect because it appears to be uncommon with other compounds, such as those that target the epidermal growth factor receptor (ERBB1). As a result, toxicity for each agent needs to be determined on a case-by-case basis [51]. Recent evaluation of cardiotoxicity [i.e., drug-related direct injury to cardiac myocytes resulting in compromised left-ventricular (LV) function] in oncology has been focused on drugs that target tyrosine kinases. It has become evident that some of these agents can cause symptomatic CHF in some patients and asymptomatic LV dysfunction in others. Thus, tyrosine-kinase-targeted therapies can either have known or likely toxicity to the heart or present a very low cardiotoxicity risk. However, exact rates of cardiotoxicity associated with tyrosine kinase inhibitors are not known since most clinical trials have not looked at predefined cardiac endpoints (i.e., LV function before and during treatment has not been measured prospectively). In addition, diagnosis of cardiotoxicity and CHF has been based mainly on medical history and physical examination, which can be considered unreliable in patients with mild to moderate grades of CHF or with asymptomatic LV dysfunction. Furthermore, it might be difficult to clinically diagnose CHF in oncologic patients who have numerous reasons other than LV dysfunction to develop shortness of

breath, fatigue, and edema. Although some trials have assessed LV function, the way the results are reported makes it complicated to place the findings in a clinically meaningful context. Moreover, some clinical trials that determine rates of CHF before the approval of a drug often exclude patients with certain comorbidities (i.e., cardiovascular disease), thus underestimating cardiac toxicity, which might be seen after approval when patients with multiple risk factors and/or cardiovascular disease are likely to be treated. Finally, most clinical trials in this setting are typically of short duration (i.e., months), whereas treatment of specific conditions with these agents might be lifelong. Currently, some kinase targets in cancer are not expressed in cardiomyocytes and, therefore, have no direct role in their survival or function [51], thus making it hard to translate successful results in oncology to potential benefits when used in cardiovascular pathology.

Existing generation of tyrosine kinase inhibitors is nonselective and the focused design of multitargeted antagonists might allow a single agent to be more effective in more types of cancer, but with an increased risk of cardiotoxicity related to inhibition of targets that are not crucial for the killing of cancer cells but that are involved in cardiomyocyte survival and function [51].

### 4.3 Promiscuous Drugs Compared to Selective Drugs

From growing experience with protein kinase inhibitors, it has been established that detailed knowledge of the drug target predicts clinical success in cancer treatment [52]. The ideal of achieving absolute specificity has been a constant aim in drug development, and the switch from mechanism to target-oriented drug discovery associated with molecular genetics and genomics faces this ideal in a strict molecular context. It is thought that a compound should preferably interact with the selected target, trigger the intended response, disengage, be metabolized, and excreted without any further effects. However, it has proven difficult to find drugs that interact specifically with one target molecule or several desired targets. [53]. There is agreement that potency and selectivity are key factors for the effectiveness and safety of any drug [4]. When designing kinase inhibitors, selectivity is a critical consideration. In fact, compounds selectivity is screened against panels of other kinases (often over 30 kinases at the same time) to determine whether there are other targets affected aside from the intended one. These panels often include specific kinases to screen for directed inhibition and/or a broad selection of kinases with structural diversity at the active site to screen for nonspecific inhibition. Once selectivity is determined in vitro, it is then determined in cellular and whole-animal systems since sometimes there are paradoxical findings [4]. The specificity of protein kinase signaling is improved by its subcellular localization since many interact with adapter proteins to direct their activity (e.g., receptors for activated C kinase for PKC and A kinase anchoring proteins for PKA). Since interaction of kinases with specific proteins is crucial for normal function, the targeted disruption of this by peptides or small-molecule inhibitors is a possible strategy for decreasing protein kinase activity. Furthermore, signaling networks can be cell-type specific, increasing the selectivity of the therapeutic agent [2]. In view of the fact that the acceptable selectivity threshold for a given inhibitor may be different for a particular disease, it may not be evident at the outset of a drug discovery program but rather after extensive experimental pharmacology and toxicology studies. Compounds without an optimal selectivity profile in vitro should in fact be evaluated under certain circumstances to understand the complex relationships between chemical structure, isoform selectivity, efficacy, and toxicity [5].

Since ATP binding is essential for the kinase's activity, the ATP binding pocket is the target of most inhibitor screens. It appears that there is enough structural diversity at these sites to predict whether selective inhibitors can be developed [4]. The binding of the drug to the substrate interaction site offers another route to increase a compound's selectivity because these sites are more diverse than the ATP binding site. This, however, may involve protein–protein interactions driven by multiple low-affinity interactions, which may be difficult to interrupt with a small molecule. Furthermore, certain peptides have been shown to have high affinity and specificity but are not orally bioavailable and cannot penetrate cell membranes. On the other hand, higher specificity might be reached by using a bisubstrate inhibitor that binds elements of both the protein substrate and ATP binding sites. Another approach is to interrupt kinase localization or its response to second messengers, and inhibition of kinase anchoring might antagonize only a subset of kinase function [2].

In order to determine the mechanisms underlying the cardiac toxicity of some tyrosine kinase inhibitors, the target and the signaling pathways mediating the adverse cardiac effects need to be identified. None of the small-molecule tyrosine kinase inhibitors are completely selective, and some (e.g., sunitinib) even seem to be rather nonselective. In some cases, kinases with no previously known role at cardiac level have been identified as key targets of these compounds (e.g., ABL with imatinib) and once a kinase is identified as critical for normal function in the heart, all agents that target that

kinase could be considered potentially toxic (i.e., as "likely" to have cardiotoxicity) [51].

Since therapeutic compounds typically present intracellular concentrations in the nanomolar range and ATP reaches levels in the millimolar range, a clinical effective protein kinase inhibitor needs to have high affinity for the target kinase several orders of magnitude higher than that of ATP. Actually, since there is this need for extremely high binding affinity to the ATP pocket and there are relative similarities of ATP pockets across protein kinase families, it may be advantageous to find other determinants in protein kinases that may confer additional specificity [4].

An important lesson was learned when selective PI3Kγ inhibitors were developed. A crucial concern was its selectivity and the effect on other PI3K isoforms. Based on viability data obtained from mouse models with genetically manipulated PI3K isoforms, it seems that small-molecule PI3K inhibitors specific for PI3Kγ should have no impact on the vital class IA PI3Ks (i.e., PI3Kα and PI3Kβ) responsible for metabolic and other "house-keeping" functions (e.g., cell growth, maintenance, and survival). Achieving this degree of selectivity would minimize unwanted side effects, but it might also decrease the therapeutic efficacy of the drug, especially in clinical settings where simultaneous modulation of different signaling pathways in addition to PI3Kγ-dependent ones might be desirable [5].

An important problem that can be encountered when considering a specific intracellular signaling pathway for therapeutic purposes is not due to drug or tissue selectivity but simply because each effector can have both adaptive and maladaptive influences on the myocardium. Therefore, a future challenge will be to translate current knowledge of the signaling mechanisms into novel pharmacological or gene therapeutic treatments for human disease such as cardiac hypertrophy, heart failure, and ACS, among others [22].

### 4.4 From Animal Models to Clinical Trials

There is a need to define the specific individual molecular phenotype and/or kinase activity profile for each patient because the clinical diagnosis in cardiovascular medicine includes a diverse spectrum of molecular profiles, and failing to do so may discard agents that could be effective in specific subsets of patients. Interestingly, the majority of early trials seem to focus on individual kinases and their role in diseases that need only short-term therapy (e.g., ACS or stroke) or where targeted local delivery is achievable. However, it is important to recognize that these may not necessarily be the disease states most likely to benefit from targeted protein kinase therapy [4].

Protein kinase signaling in the cardiovascular system is mainly studied in cultured cells (e.g., neonatal cardiomyocytes), and the results may not reflect what happens in fully differentiated adult cells or in vivo. However, it has been established that studies performed in cultured cells are valuable because these cells naturally grow and divide in a stable manner, they form intercellular connections, and are readily available. Then again, there are noteworthy differences between cultured cells and fully differentiated adult cells, such as expression of protein kinases, their subcellular localization, their protein substrates, and the interaction between GPCRs and protein kinases that rule the responses to their activation/inhibition. In fact, experimental models that combine genetic and pharmacologic manipulation of protein kinase activity are attractive to determine in vivo the role of the different protein kinases in disease mechanisms. Many of the early in vivo validation studies are commonly performed in murine models, and further validation of the findings in larger animal models is important since there are differences in heart rate, metabolism, cellular calcium handling, and action potential durations between mice and humans [2].

In the complex process of drug development, there are numerous steps that lie between target selection and the initiation of phase II or proof-of-concept human clinical trials. The screening and hit identification of an agent is followed by several rounds of compound optimization focused on pharmacological and toxicological testing and, eventually, pharmaceutical development and production. Drug development requires the correct expertise, appropriate time, and resources to move from the initial concept to the every day practice. The crucial questions concern target validation (to define whether modulating the target activity will alter the course of human disease without causing any significant adverse effects) and practical development (to define whether compounds that will modulate the target's activity in the living organism with appropriate potency and specificity can be found) [5]. There are some reservations to the use of genetically modified animals in terms of their relevance to human disease. There are certain concerns regarding compensation during early development, intracellular changes (absence/excess of protein compared to absent/increased catalytic activity, complete and permanent versus inducible and dose-dependent loss/gain of activity) and inherent differences of animal disease models compared to human disease [5].

The effort to identify new pharmacological therapies for cardiovascular disease continues; however, for certain pathologies (e.g., heart failure) it appears that the pace is slowing considerably. This may be associated with the high cost of drug development, the perceived risk–return ratio, and the complexity of conducting nec-

essary clinical trials to obtain registration. For example, it has been estimated that the cost of a large-scale heart failure trial ranges between $102 and 207 million, and recent negative or adverse trials (e.g., OVERTURE with omapatrilat and MOXCON with moxonidine) may trigger certain reservations. This may be combined with the fact that drug development may be affected or limited by the need of highly selective agonists or antagonists that target cardiac isoforms exclusively or, instead, will depend on the concomitant use of specific targeted therapeutic delivery to the heart [21].

## 5 CONCLUSIONS AND FUTURE PERSPECTIVES

Agents that target protein kinases have been used successfully in oncology, and several have been tested in cardiology with mixed results, suggesting that in the future selective protein kinase inhibitors may be used to treat cardiovascular disease [4].

The intracellular signal transduction network is highly complex and redundant; hence, the challenge of developing a successful targeted therapy is not small. Nevertheless, the signaling pathways associated with disease are being gradually unraveled, encouraging the development of safe and effective drugs that specifically and selectively target protein kinases [5]. Refinement of the selectivity of protein kinases inhibitors may decrease its toxicity while producing more biological effects compared with drugs that inhibit upstream activation [2].

Dormant problems of modulating protein kinases are not small; its use may dysregulate a completely different organ (e.g., inducing apoptosis could reduce ischemia-induced cell death in cardiomyocytes but might favor tumor promotion in other organs). Notwithstanding, protein kinases are unraveling a new and exciting area of knowledge in cardiovascular disease. Developing new agents that selectively and safely inhibit protein kinases may provide a new therapeutic line of agents that may be used in ischemic heart disease, congestive heart failure, pulmonary and systemic hypertension, and arrhythmias.

# STATINS IN THE REDUCTION OF CARDIOVASCULAR EVENTS

Rajesh Sachdeva, Bradley Hughes, and Jawahar L. Mehta
*Division of Cardiovascular Medicine, Central Arkansas Veterans Healthcare System and The University of Arkansas for Medical Sciences, Little Rock, Arkansas*

## 1 DISCOVERY OF STATINS

In the 1960s, physicians became aware of cholesterol's role in the development of atherosclerotic heart disease. Several agents, such as nicotinic acid, cholestyramine, and clofibrate were developed, but these agents failed to substantially lower low-density lipoprotein (LDL)-cholesterol levels. Akira Endo, a Japanese scientist who had done years of research on fungi, realized that fungi could hold a solution to the cholesterol problem because bacteria—like humans—required cholesterol to maintain cell wall integrity. He reasoned that certain fungi produce a substance that destroys cholesterol in bacterial cell wall as an evolutionary adaptation. With this fundamental understanding, he set about testing more than 6000 fungal broths. In 1973, he identified the mold *Penicillium citrinum* that produced a substance that appeared to inhibit HMG-CoA reductase enzyme, a key step in LDL-cholesterol synthesis. This substance, named compactin, was the first known statin. It successfully lowered LDL-cholesterol levels in animal studies, and similar success was seen in early human trials. Interestingly enough, the first patient treated with Dr. Endo's new drug developed severe muscle cramps and weakness, now a well-known side effect of this class of drugs, and had to discontinue therapy. However, interest in this agent continued to grow as its success in lowering LDL-cholesterol became public knowledge, and several pharmaceutical companies developed several variations of this formulation. Merck was first to market lovastatin (Mevacor) in the United States in 1987. Today the world's most widely selling drug is a statin (atorvastatin, Lipitor; Pfizer), with annual worldwide sales of $12 billion [1].

## 2 STATINS: BIOCHEMISTRY AND MECHANISMS OF ACTION

Acetyl-CoA is produced from glucose, fatty acids, or essential amino acids, with three molecules of acetyl-CoA combining to form 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA). HMG-CoA reductase catalyzes the reduction of HMG-CoA to produce mevalonate. Mevalonate produces isoprene units that condense to form squalene, and the cyclization of squalene produces the steroid ring system, with subsequent reactions generating cholesterol. HMG-CoA reductase is the rate-limiting step in the formation of cholesterol in the liver and intestine, though cholesterol formation does occur in most cells of the body (Fig. 1).

Statins compete with normal substrate for the enzyme's active binding site and once bound alter the conformation of the enzyme. This binding is reversible, but once statin binds to HMG-CoA reductase, the enzyme is prevented from attaining a functional conformation. The inhibition of HMG-CoA reductase by statins reduces the hepatocyte cholesterol content,

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad

**Figure 1** Inhibition of HMG-CoA reductase by statins decreases the synthesis of isoprenoids and cholesterol. The isoprenoid, geranylgeranyl (GG), is an important lipid attachment for Rho, which permits the subsequent membrane translocation and activation of Rho and Rho kinase. Inhibition of Rho/Rho-kinase activity by statins leads to increase in eNOS expression and activity.

which subsequently upregulates the expression of LDL receptors, resulting in increased removal of LDL-cholesterol from the circulation. Statins also inhibit hepatic synthesis of apolipoprotein B-100, which results in a reduction in the synthesis and secretion of triglyceride-rich lipoproteins [2].

Statins are widely used for their LDL-cholesterol-lowering properties. Initial LDL-lowering ability varies among different statins, but with doubling of dose of any given statin, an additional 7% reduction in LDL-cholesterol can be expected. Statins also have effects on other components of the lipid profile. A reduction of triglyceride level by as much as 45% can be seen in patients with hypertriglyceridemia, and this reduction occurs via a reduction in hepatic secretion of very low density lipoprotein (VLDL). Statins also have a minor impact on high-density lipoprotein (HDL)-cholesterol levels increasing it by 5–10% [3].

## 3 STATINS: EXPERIMENTAL AND CLINICAL STUDIES

Long- and short-term trials with statins have demonstrated significant reductions in cardiovascular events in patients with and without a history of coronary heart disease (CHD). Statins are well-established LDL-cholesterol-lowering agents, but the benefit of statins exceeds that seen at a particularly low LDL-cholesterol level, which occurs naturally. This raises the issue that besides improving the lipid profile, statins have nonlipid properties that ultimately result in reduction in atherothrombosis. These effects arise through the inhibition of several mevalonate-derived metabolites other than cholesterol itself, which are involved in the control of different cellular functions. Although statins represent the reference in the prevention and treatment of CHD, combination therapy with other lipid-lowering drugs may increase their therapeutic potential.

### 3.1 Animal Studies

Initial trials of the first statin (compactin) in 1973 were disheartening. Dr. Endo initially tested his discovery in rats with disappointing results. Continued research led to the understanding that rats differ in the mechanisms by which they carry out cholesterol synthesis. Dr. Endo then tested statins in chickens with much more promising results.

With greater understanding of how animals metabolize cholesterol, selection of animal models for use in studies has improved. We now know that rats are generally resistant to atherosclerosis without genetic manipulation. Monkeys, baboons, and pigs have proven to be very good animal models, as they develop atherosclerosis in a manner similar to humans. In recent studies, animals have been genetically modified (apo-E knockout and LDL-receptor knockout mice) that develop atherosclerosis rapidly when fed diets rich in cholesterol. In these animals, statin therapy decreases aortic cholesterol accumulation, reduces the extent of atherosclerosis, and prevents diet-induced increase in LDL-cholesterol levels. These studies have shown preserved tissue superoxide dismutase activity (protective against free radicals), inhibition of LDL-cholesterol oxidation by activated macrophages, and interference with atherosclerotic lesion development by reducing intimal thickening and the expression of the cytotoxic inducible nitric oxidize synthase (iNOS). Statins have also been shown to inhibit smooth muscle cell proliferation. It is unclear if similar results are reproduced in humans at clinically relevant doses.

### 3.2 Human Studies

***Primary Prevention Trials*** Initial animal studies illustrated a connection between atherosclerotic CHD and serum lipid levels. This understanding led to the logical next step of evaluating lesion progression or regression with statin therapy. These trials were initially called "regression trials," due to the supposition that lipid-lowering therapies would cause plaque regression. Multiple large trials have proven that atherosclerotic lesions do not actually regress with statin therapy, but

progression of lesions may be slowed with a reduction in serum LDL-cholesterol levels [4]. A large number of clinical studies have shown that the statin group of drugs are effective in primary and secondary prevention of cardiovascular events. Details of these trials are given elsewhere. Here we discuss results of some large trials.

The Scandinavian Simvastatin Survival Study (4S) included 4444 Scandinavian patients and clearly showed the life-saving potential of statins [5]. However, many surprising benefits in addition to slowed atherosclerosis-related events became evident in this study. For example, it became clear that simvastatin can lower cardiovascular events regardless of baseline LDL-cholesterol, HDL-cholesterol, and triglyceride levels. The West of Scotland Coronary Prevention Study (WOSCOPS) [6] evaluated the benefit of another statin, pravastatin, on the rate of nonfatal myocardial infarction (MI) and CHD-related deaths in 6595 men with hypercholesterolemia and no prior evidence of MI or revascularization. At 5 years of follow-up, there was an absolute reduction in nonfatal MI or CHD death of 3%, and the reduction in clinical events began within 6 months of randomization. This study also showed that there was no difference in noncardiovascular death or incidence of cancer among participants.

The Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/Tex CAPS) [7] was a randomized, placebo-controlled trial of lovastatin in 6605 patients without CHD. After a 5-year follow-up, for every 1000 men and women treated with lovastatin, 19 coronary events, 12 MIs, and 17 coronary revascularizations could be prevented, and this benefit was independent of changes in LDL-cholesterol. This study extended the results seen in WOSCOPS in two ways: It demonstrated the efficacy of primary prevention in women, and it demonstrated the efficacy of primary prevention in patients with "normal" serum LDL-cholesterol levels at the time of enrollment. The results of this study led to major revisions in the National Cholesterol Education Program (NCEP) Adult Treatment Panel III guidelines.

The Medical Research Council/British Heart Foundation (MRC/BHF) Heart Protection Study (HPS) assigned 20,536 subjects to treatment with either simvastatin (40 mg/day) or placebo. This study included patients with known CHD, occlusive arterial disease, and diabetes, making this study relevant in primary as well as secondary prevention. After 5 years of follow-up, there was no effect of statin therapy on the incidence of noncardiovascular deaths, but there was a significant reduction in ischemic strokes without an increase in hemorrhagic strokes [8]. This study showed benefit in men and women, older adults, and patients at risk for cardiovascular events regardless of baseline LDL-cholesterol level.

The recently completed Anglo-Scandinavian Cardiac Outcomes Trial—Lipid Lowering Arm (ASCOT-LLA) included 19,342 subjects with hypertension and at least 3 other cardiovascular risk factors [9]. Participants in this study were randomized to therapy with atorvastatin or placebo, in addition to standard antihypertensive therapy. This study was halted prematurely after 3 years when the lipid-lowering arm of ASCOT showed a 36% reduction in fatal CHD and nonfatal MI compared with the placebo group.

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) included 10,355 hypertensive patients who were randomized to therapy with either pravastatin or standard antihypertensive therapy. No significant benefits in terms of all-cause mortality or coronary and stroke events were apparent with statin use in this study [10]. This may be explained by the use of statins by a large number of subjects in the usual care group, leading to a smaller difference in total and LDL-cholesterol levels.

The Prospective Study of Pravastatin in the Elderly at Risk (PROSPER) included 5804 patients aged 70–82 years with a history of, or risk factors for, vascular disease [11]. Again, this study was designed as a primary and secondary prevention trial. Patients were randomized to pravastatin (40 mg) or placebo, and the follow-up period was 3.2 years. Primary endpoints (a composite of CHD death, nonfatal MI, and fatal or nonfatal stroke) were reduced by 15%. The CHD death rate was reduced by 24%, and although the incidence of transient ischemic attack was reduced, there was no reduction in stroke rate.

***Secondary Prevention Trials*** With the promising data available from these and other primary prevention trials, and the fundamental understanding that statin therapy clearly reduced serum LDL-cholesterol levels, the application of statin therapy in high-risk groups seemed promising. The absolute risk for an event is clearly highest in secondary prevention or high-risk groups, and lowest in primary or low-risk groups. Most studies were based on Framingham criteria (age, fasting LDL-cholesterol level, HDL-cholesterol level, blood pressure, diabetes, and smoking status).

Since 1994, there have been a total of six published prospective, double-blind, placebo-controlled, randomized trials with statin treatment in high-risk patient populations. These are the 4S, the Cholesterol and Recurrent Events (CARE) trial, Long-Term Intervention with Pravastatin in Ischemic Disease (LIPID), HPS, the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER), and the ASCOT-LLA. All six of these

studies showed significant reduction in total cholesterol, LDL-cholesterol, and triglycerides, with an increase (or at least no reduction) in HDL-cholesterol. These studies also showed absolute relative risk reduction in all-cause mortality, fatal cardiac heart disease, and nonfatal MI, fatal and nonfatal stroke, need for revascularization, and any major vascular event.

This vast experience with both primary and secondary prevention trials led to rapid advances in current guidelines for the management of patients with cardiovascular disease. Further examination of such trial data has led to the recommendation that treatment goals for LDL-cholesterol should be the reduction of LDL-cholesterol levels to less than 100 mg/dL in moderate-risk patients and less than 70 mg/dL for high-risk patients. The beneficial effects of statins in addition to their LDL-cholesterol-lowering effects, include a reduction in inflammation, improvement in vascular function, and other pleiotropic effects, but it is not yet clear how much of the "statin effect" is related to these additional nonspecific properties [4].

## 4 STATINS: NEW ISSUES

### 4.1 Pleiotropic Effects

The pleiotropic effect of a drug refers to actions in addition to those for which the drug was specifically developed. These effects may or may not be related to the primary mechanism of the drug, and they may or may not be desirable. Such effects are, by definition, unanticipated. In addition to the well-documented beneficial effects of statins on lipid profiles, a number of studies have identified potentially other beneficial effects of statins (Table 1). Specific examples of such unanticipated effects of statins currently under investigation include the improvement in endothelial function, increased bioavailability of nitric oxide (NO), vasomotion, antioxidant and anti-inflammatory effects, and stimulation of endothelial progenitor cell recruitment.

**TABLE 1 Non-Lipid-Lowering Effects of Statins**

| |
|---|
| **Anti-Thrombotic Effects** |
| Reduction in PAI-1 |
| Increase in t-PA |
| Increase in NOS expression and activity |
| Reduction in tissue factor expression |
| Reduction in fibrinogen |
| Decreased platelet aggregation |
| Increase in thrombomodulin |
| **Effects on Endothelial Cell Biology** |
| Enhanced eNOS expression and activity |
| Reduction in genes for leukocyte adhesion and inflammatory signals |
| Reduction in endothelial permeability |
| Increased endothelial growth |
| Increase in endothelial progenitor cells/angiogenesis |
| Reduction in pre – pro ET-1 expression |
| **Effects on Vascular Smooth Muscle Cells** |
| Reduction in VSMC growth and migration |
| Decrease in expression of AT1 receptor in response to injurious stimuli |
| **Miscellaneous Effects** |
| Reduction in generation of oxidant species |
| Increase in gene expression of antioxidants |
| Decrease in fibroblast growth and collagen formation |
| Inhibition of LDL oxidation and ox-LDL uptake |
| Inhibition of mitogen-stimulated T and B-lymphocyte proliferation |
| Inhibition of expression of class II MHC |
| Blockade of the effects of angiotensin II |
| Inhibitor of natural killer cell cytotoxicity |
| Stimulation of bone formation |

PAI-1: plasminogen activator inhibitor type 1; t-PA: tissue plasminogen activator; ET-1: endothelin-1; VSMC: vascular smooth muscle cell; AT1: angiotensin II type 1; ox-LDL: oxidized low density lipoprotein; MHC: major histocompatibility complex.

*Source*: This table has previously been published and is reproduced with the permission of the publisher.

***Improvement in Endothelial Function/Increased Bioavailability of Nitric Oxide*** Long recognized as an inciting event in atherogenesis, endothelial dysfunction is an early but as-yet poorly understood process. The vascular endothelium closely regulates the contractile state of the vascular wall. Hypercholesterolemia impairs endothelial function, and this is often characterized by a paradoxical vasoconstriction caused by acetylcholine in response to an impaired synthesis, release, and activity of endothelium-derived NO. Abnormalities in endothelium-dependent vasomotor responses predict future progression of atherosclerosis and coronary events. Statins have been shown to enhance the expression of endothelial NO synthase (eNOS), the enzyme that catalyzes the formation of NO from L-arginine eNOS is generally downregulated in atherosclerosis, and the salutary effect of statins on eNOS may be mediated by the ability of LDL-cholesterol to increase the level of caveolin-1, an inhibitor of eNOS activity. Statins also enhance eNOS activity, thereby increasing the bioavailability of NO [12, 13]. Several mechanisms are likely involved, ranging from the reduction in the production of reactive oxygen species, which inactivate NO, and to the stabilization of eNOS messenger ribonucleic acid (RNA) [12].

As discussed above, treatment with statins to improve endothelial function, though the exact mechanism by which this occurs is as yet not clear. In a study of hypercholesterolemic patients, treatment with fluvastatin for 6–12 weeks improved myocardial perfusion in previously ischemic segments, and the improvement in perfu-

sion was greater than that seen in normal segments [14]. In another study of patients with moderately elevated cholesterol levels, treatment with simvastatin increased vasodilatory response to acetylcholine as determined by forearm blood flow. This improvement in blood flow continued to increase over the duration of treatment [15]. Other studies have compared changes in vasomotion after statin therapy to either dietary modifications or placebo, with significant improvement seen only in the statin group. These improvements appear to occur regardless of serum cholesterol levels or C-reactive protein (CRP) levels, and indeed they appear within hours of initiation of statin therapy—long before any lipid-lowering effect is appreciated. The normalized vasomotion achieved with statins has also been shown to occur in high-risk groups, such as diabetics.

***Antioxidant Effects*** Statins inhibit oxidation of LDL-cholesterol both in vitro and ex vivo, in addition to their ability to reverse the inhibitory effect of oxidized LDL-cholesterol on eNOS expression and activity. Statins have also been shown to inhibit the oxidation of LDL-cholesterol as well as HDL-cholesterol. In addition, statins have been shown to exert free-radical scavenging effect that may contribute to the inhibition of lipoprotein oxidation [17]. Statins also indirectly inhibit normal oxidative mechanisms by decreasing the ability of macrophages to oxidize lipoproteins, although the exact mechanism of this effect is still under investigation. In studies on the antioxidant effects of statins, the benefits were seen within days of initiation of treatment with statins, long before serum LDL-cholesterol levels were altered.

***Anti-Inflammatory Effects*** In the recent past, a large number of studies have revealed the importance of inflammation in the development of atherosclerosis. Elevated serum markers of inflammation such as (CRP), interleukin-6, intercellular adhesion molecule-1, and serum amyloid A have all been shown to be associated with increased risk for cardiovascular events. While the precise cause–effect relationship between these markers and overt cardiovascular disease remains elusive, statin therapy has been shown to lower the serum levels of these markers in humans. In the CARE trial, long-term follow-up showed that subjects with elevated CRP levels benefited most from provastatin [16]. In this study, reduction of CRP levels was not correlated with a reduction of serum LDL-cholesterol levels. Other studies have shown a reduction in CRP levels shortly after initiation of statin therapy and long before serum LDL-cholesterol levels decline. It has been postulated that this rapid reduction in CRP could potentially explain the early benefits of these drugs seen in acute coronary syndromes. However, no study has yet shown that statins can decrease CRP levels independent of LDL-cholesterol levels and reduce cardiovascular events.

***Plaque Regression/Stabilization*** Elegant studies in animal models have shown the plaque-stabilizing effects of statins. While a portion of this effect may be due to reduction in serum LDL-cholesterol levels, statins have also been shown to inhibit uptake of oxidized LDL-cholesterol by cluster of differentiation 36 scavenger receptor (CD-36), scavenger receptor A, and lectin-like oxidized LDL (LOX-1) receptors as well as inhibit macrophage oxidative properties. As mentioned above, elevated serum levels of inflammatory markers have been shown to portend poor outcomes. There is emerging data to suggest that some of these poor outcomes may be mediated by plaque rupture. Weakening of the fibrous cap in such unstable plaques is associated with increased macrophage production of matrix metalloproteinases. In human studies, statins have been shown to change the composition of such plaques in a way that favors stabilization. After statin treatment, such plaques are composed of less lipid and oxidized LDL-cholesterol, fewer macrophages, and fewer T cells. In addition, such plaques have higher collagen content and less matrix metalloproteinase immunoreactivity, as well as reduced rates of apoptosis [12]. These promising plaque-stabilizing effects of statins may also potentially explain the usefulness of this class of drugs in acute coronary syndromes.

***Stimulation of Endothelial Progenitor Cells*** Statins have shown promise in the prevention of vascular ischemic injury. Statins also play an important role in repair of vascular injury by augmenting endothelial progenitor cell differentiation. Work in humans has shown that statins are at least as effective as vascular endothelial growth factor, a key cytokine in the regulation of neovascularization, in stimulating this endothelial progenitor cell differentiation. In addition to this augmentation, statins have also been shown to increase the number of endothelial progenitor cells, which subsequently improve ischemia-induced neovascularization, accelerates reendothelialization after injury, and improves postischemic cardiac function [4]. As with so many of the pleiotropic effects of statins, these effects were seen at time intervals much shorter than those required for modulation of serum LDL-cholesterol levels.

***Immunomodulation*** Increasing evidence suggests that statins may act as immunomodulators. With this realization, these agents have been used in solid organ transplant recipients. Statins have been shown to decrease interferon-induced major histocompatibility complex-II (MHC-II) in human endothelial cells and macrohpages. This effect is reversed by mevalonate and

has been attributed to the inhibitory effect of statins on promoter IV of MHC-II transactivating factor, which leads to suppression of T-lymphocyte activation. This suppression of T-helper-cell-I immune response is the proposed mechanism for the benefits seen in solid organ transplant recipients.

### 4.2 Combination with Other Drugs

***Ezetimibe*** Ezetimibe, a potent intestinal cholesterol absorption inhibitor, offers the potential address the question of whether all the effects of statins can be attributed to their cholesterol-lowering benefits. Ezetimibe significantly lowers LDL-cholesterol levels when used as monotherapy or in combination with statins. Indeed, ezetimibe is often used in combination with statins in high-risk patients who require aggressive lipid-lowering therapy to achieve an appropriate serum LDL-cholesterol level. In a recent study, forearm blood flow responses to acetylcholine and sodium nitroprusside were measured in patients with stable coronary artery disease (CAD) after 4 weeks of therapy. After 4 weeks of therapy, LDL-cholesterol levels were reduced in all patients; however, in the ezetimibe group, there was no increase in acetylcholine-mediated forearm blood flow response. In contrast, dose escalation of atorvastatin or de novo atorvastatin monotherapy was associated with a significant improvement in acetylcholine-mediated forearm blood flow response [17]. This study shows that while ezetimibe effectively lowers LDL-cholesterol levels, only statin therapy was associated with improved vasodilator function. However, whether LDL-cholesterol reduction with ezetamide offers the same benefits as that with statins is not yet known.

***Niacin/Fibrates*** Reduction of LDL-cholesterol with statin therapy is currently identified in treatment guidelines as the primary focus for patients with or at risk of CHD. Yet despite effective statin therapy, there is still an unacceptably high residual coronary risk. A substantial proportion of patients with CHD have mixed dyslipidemia, including low levels of HDL-cholesterol, an independent and predictive risk factor for CHD. Although effective in reducing LDL-cholesterol, statin therapy has only modest effects in raising HDL-cholesterol. Fibrate therapy is an alternative lipid-modifying strategy, and is effective in reducing CHD mortality and morbidity, with the magnitude of clinical benefit similar to statin therapy.

Multidrug therapy with complementary mechanisms of action has been proposed as a means of improving lipid-modifying efficacy. Nicotinic acid is the most potent agent for increasing HDL-cholesterol and also substantially reduces LDL-cholesterol and triglycerides. Addition of nicotinic acid to statin therapy would be a logical management approach, given the potential for complementary therapeutic benefit. The clinical benefits of this combination are supported by the results of the HDL Atherosclerosis Treatment Study (HATS), which showed reduction of 60–90% in the incidence of major CAD events when both agents were administered. In addition, combination treatment led to angiographic regression of coronary stenosis, compared with placebo, rather than slowed progression as previously reported with statin monotherapy. Given that the prevalence of low HDL-cholesterol, particularly among individuals with CHD, is higher than previously anticipated, combining nicotinic acid and a statin represents an innovative approach to further reducing CHD risk.

To date, the most compelling evidence that the concentration of HDL-cholesterol is a strong, independent, inverse predictor of coronary heart disease risk comes from the Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT) and the Helsinki Heart Study (HHS). In VA-HIT, CHD patients randomized to gemfibrozil experienced a 6% increase in HDL-cholesterol, a 31% decrease in plasma triglycerides, and no change in LDL-cholesterol. Major coronary events were reduced by 22% compared with placebo. The change in HDL-cholesterol was significantly associated with reductions in coronary events, whereas the change in triglycerides was not. Statins when combined with fibrates have potentially beneficial effects on HDL-cholesterol in addition to LDL-cholesterol. However, fibrate addition to statin therapy increases the risk of hepatic injury.

***Cholestery Transfer Protein (CETP) Inhibitors*** Some years ago, a mutation in the CETP gene was discovered in a select Japanese population. This mutation was accompanied by a substantial increase in HDL-cholestrol. Because HDL-cholesterol regulates reverse cholesterol transport and has antioxidant, antithrombotic, and anti-inflammatory properties, the prevalence of atherosclerotic disease is low in Japanese. Epidemiological studies were undertaken to define the prevalence of the mutation. These studies suggested that the mutation occurred in 11% of the Japanese population and that affected individuals were resistant to atherosclerosis [18, 19]. These epidemiological data triggered interest in the biochemical characteristics of CETP.

High CETP concentration has been associated with more rapid progression of CAD, and statin therapy is more effective in this population, independent of baseline or on-treatment lipid levels, suggesting that the plasma CETP level may be an important determinant

of the response to statins [20]. Statins reduce plasma CETP activity by 5–10% and cholesteryl ester transfer by 35% [20–28]. For instance, atorvastatin reduces CETP activity by 7%, and cholesterol transfer from HDL to non-HDL-cholesterol particles is reduced by 37% [27, 28]. The magnitude of these effects is modified by the CETP genotype [29, 30]. Because statins alone cause a substantial decrease in triglyceride level and a small increase in HDL-cholesterol, one might speculate that the combination of a statin with a CETP inhibitor would be more effective than either therapy alone.

Recently, a new class of drugs, CETP inhibitors, has been developed. Torcetrapib and JTT-705 are currently in the preliminary stages of clinical development. JTT-705 in combination with pravastatin has been assessed in a randomized, double-blind, placebo-controlled trial conducted in 152 individuals with elevated LDL-cholesterol. This agent increased HDL-cholesterol by 30% [31]. Torcetracip has been studied alone and with atrovastatin [32]. Torcetrapib increases HDL-cholesterol from 60 to 120%, and a number of clinical trials are underway to examine if torcetrapib with statins reduces cardiovascular events more than statins, and if yes, are there associated side effects?

***Combination with Fish Oil*** There is clear evidence that statins are effective agents for lowering LDL-cholesterol and reducing mortality in patients with CHD. Omega-3 polyunsaturated fatty acids (PUFA) have been shown to reduce serum triglyceride levels, a condition that often persists after treatment with statins. In many early small clinical trials, there was evidence that omega-3 PUFA supplementation lowered CHD mortality; however, in all of these studies, patients were not receiving doses that would be expected to significantly lower serum triglyceride levels. Early enthusiasm over fish oil supplementation was also limited by data suggesting that daily dietary supplementation with omega-3 PUFA resulted in an undesirable increase in serum LDL-cholesterol.

Subsequent studies have shown that treatment with omega-3 PUFA in combination with statin therapy, and at doses sufficient to lower serum triglyceride levels, was generally well tolerated and safe. Other research has shown no adverse effects on LDL-cholesterol and no adverse interactions with statin treatment [33]. This new understanding has led to more widespread use of combined therapy with statins and omega-3 PUFA in patients with both elevated serum LDL-cholesterol levels and elevated triglyceride levels [34].

***Combination with Aspirin*** Aspirin has long been recognized for its immediate antiplatelet effect, and this has led to its widespread use in both acute coronary syndromes and as a preventative therapeutic measure. Statins are now widely used for their delayed antiatherogenic effect. Recent studies have examined the possibility of additive clinical benefits with combination (aspirin+statin) therapy. Recently published guidelines for statin and aspirin use indicate a favorable risk–benefit ratio for all patients who have survived prior cardiovascular events, and indeed, the U.S. Food and Drug Administration (FDA) has approved the use of combination therapy with aspirin and statin in the secondary prevention of cardiovascular disease.

Meta-analyses have shown relative risk reductions for fatal or nonfatal MI of 31% for pravastatin plus aspirin versus aspirin alone, and 26% for pravastatin plus aspirin versus pravastatin alone. For the composite endpoint of CHD death, nonfatal MI, coronary artery bypass graft, percutaneous transluminal coronary angioplasty, or ischemic stroke, similar relative risk reductions were seen. Despite these findings, there remains widespread underutilization of this effective drug combination [35].

***Combination with Peroxisome Proliferator-activated Receptor (PPAR) Activators*** Inhibition of cardiac remodeling has rapidly come to the forefront in long-term management of postinfarction patients, and statins have recently been recognized for their beneficial effects in prevention of adverse cardiac remodeling in the post-MI patient. Angiotensin II is known to enhance collagen synthesis, and it is this enhanced collagen synthesis that is felt to play a key role in cardiac remodeling following injury. Increased levels of angiotensin II have been shown in a mouse model to induce oxidative stress and procollagen-I expression in cardiac fibroblasts. In recently published studies, it has been shown that both pravastatin and pioglitazone, a member of the PPAR class of agents, both individually block the effect of angiotensin II, and both agents affect differing pathways. The combination of these agents appears to have an additive effect in terms of reduced myocyte oxidative stress and increased inhibition of procollagen I formation. While trials in humans have yet to be reported, these promising results in animal models point to another potential powerful use of statins for their cardioprotective effects [36].

***Combination with Antiplatelet Agents*** The early realization that clopidogrel and atorvastatin are competitive substrates for the cytochrome P450 3A4 (CYP3A4) hepatic enzyme system caused much concern. Because clopidogrel has low bioavailability, because atorvastatin has a higher affinity for the substrate binding site than does clopidogrel, and because atorvastatin has a long half-life, atorvastatin inhibits the ability of clopidogrel

to be metabolized into its active metabolite in a dose-dependent manner. A 600-mg loading dose of clopidogrel will overcome this competitive binding, but neither a 300-mg loading dose or the daily 75-mg dose of clopidogrel are sufficient to prevent atorvastatin from decreasing the metabolism of clopidogrel. The clinical significance of this drug–drug interaction remains, as yet, unclear. It is clear that other statins, namely pravastatin and fluvastatin, which are not metabolized via the hepatic CYP3A4 system, have little to no effect on metabolism of clopidogrel. However, it should be pointed out that it remains unclear today whether this potential interaction between atorvastatin and clopidogrel is clinically significant [37, 38].

## 5 WITHDRAWAL PHENOMENON

Despite the well-recognized beneficial effects of statins, there have been patients who have abruptly discontinued their use due to financial constraints, intolerable side effects, or mere forgetfulness. Several studies have shown an increased incidence of cardiac events in patients with atherosclerotic heart disease after abrupt cessation of statin therapy. In fact, one study showed a rapid increase in CRP and interleukin-6 levels in patients with hypercholesterolemia after abrupt cessation of statin therapy [39]. This study has led many to propose that the increased inflammatory response seen after such abrupt cessation of statin therapy may explain the increased incidence of cardiovascular events. Regardless of the mechanism of this phenomenon, statin therapy should not be abruptly discontinued.

## 6 OTHER DISEASE STATES

### 6.1 Aortic Stenosis

Once thought to be simply a "wear-and-tear" phenomenon, it is now thought that aortic stenosis has some pathological similarities with atherosclerotic disease. Lipid deposition and macrophage infiltration, with subsequent inflammation, now appears to be the common pathophysiologic process between the two conditions. There are studies that show accelerated progression of aortic stenosis in patients with hyperlipidemia, and the similarities among risk factors for aortic stenosis and atherosclerotic disease has led to attempts to slow the progression of aortic stenosis with statin therapy. Several small studies have reported reductions in aortic valve calcium accumulation, smaller increases in mean gradients across stenotic aortic valves, and reductions in progression of aortic stenosis in patients treated with statins (Table 2) [40–46]. This new understanding of the pathophysiology of aortic stenosis and the promising early data indicate that statins may have an increasing role to play in the management of aortic stenosis. However, a recent large study showed that intensive statin therapy does not halt the progression of calcific aortic stenosis or induce its regression [47].

### 6.2 Alzheimer's Disease

The pathological hallmark of Alzheimer's disease is the accumulation of β-amyloid neurofibrillatory plaques in the central nervous system tissue. Accumulation of β-amyloid is a result of abnormal proteolytic processing of amyloid precursor protein (APP), and there is evidence that this abnormal processing of APP is mediated by cholesterol [48]. Indeed, in transgenic mice overexpressing APP, a high-cholesterol diet significantly increases the level of β-amyloid plaques in the brain. When these mice were treated with cholesterol-lowering drugs, the β-amyloid plaque burden in the central nervous system (CNS) was decreased. This finding led to interest in the use of cholesterol-lowering agents as a preventative approach to Alzheimer's dementia. However, studies in humans have failed to substantiate this theory. In one recent study, after adjusting for age, gender, education, comorbid vascular disease, body mass index, and history of lipid-lowering drug therapy, there was no association between total LDL- or HDL-cholesterol and risk of dementia or Alzheimer's disease [49].

### 6.3 Bone Degeneration

Estrogen replacement therapy, selective estrogen receptor modulators, and bisphosphonates—all current therapies for treatment of osteoporosis—are focused on blunting the resorption phase of bone remodeling. Bone morphogenic protein-2 (BMP-2), a central growth factor in osteoblast differentiation, is incorporated into bone matrix during bone formation. It is later released, in active form, during bone resorption. BMPs are responsible for enhancing osteoclast differentiation, including stimulation of expression of the structural proteins of bone. Statins have been shown to stimulate transcription of BMP-2, and, therefore, enhance the process of osteoblast differentiation and new bone formation. Recent studies have indeed shown increases in bone mineral density and reduced fracture rates in patients treated with statins. One caveat in this arena is that all of the currently available statins are metabolized in the liver; therefore, their delivery to bone is greatly reduced. Further research into delivery of statins to bone, perhaps through skin patches, is needed [4].

**TABLE 2 Nonrandomized Retrospective Studies of Medical Therapy to Prevent Progression of Calcific Aortic Stenosis**

| First Author, Year | No. of Subjects | Mean Age (year) (% Male) | Mean F/U Interval (year) | Study Groups | Parameter Reported | *p-value* |
|---|---|---|---|---|---|---|
| EBT[a] calcium | | | | | | |
| Pohle 2001 [41] | 104 | 65 (86) | 1.25 | | Increase in valve calcium (per year) | |
| | | | | LDL ≤ 130 mg/dL | 9 ± 22% | ≤0.001 |
| | | | | LDL ≥ 130 mg/dL | 43 ± 44% | |
| Shavelle 2002 [42] | 65 | 67 | 2.5 | | Increase in valve calcium (per year) | |
| | | | | Statin therapy (43%) | 12.1% | 0.006 |
| | | | | No statin therapy | 32% | |
| Echocardiography | | | | | | |
| Aronow 2001 [43] | 180 | 82 (31) | 2.8 | | Increase in peak gradient (mmHg/year) | |
| | | | | LDL ≥ 125 mg/dL, not on statin | 6.3 ± 1.4 | <0.0001 |
| | | | | LDL ≥ 125 mg/dL, on statin | 3.4 ± 1.0 | |
| | | | | LDL ≤ 125 mg/dL, not on statin | 3.1 ± 1.1 | |
| Novaro 2001 [44] | 174 | 68 (44) | 1.8 | | Decrease in valve area ($cm^2$/year) | 0.03 |
| | | | | Statin therapy (33%) | 0.06 ± 0.016 | |
| | | | | No statin therapy | 0.11 ± 0.18 | |
| Bellamy 2002 [45] | 156 | 77 (58) | 3.7 | | Decrease in valve area ($cm^2$/year) | 0.04 |
| | | | | Statin therapy (24%) | 0.04 ± 0.15 | |
| | | | | No statin therapy | 0.09 ± 0.17 | |
| Rosenhek 2004 [46] | 211 | 70 (51) | 2.0 | | Increase in aortic velocity ($m.s^{-1}.y^{-1}$) | |
| | | | | Statin therapy | 0.10 ± 0.41 | 0.0001 |
| | | | | No statin therapy | 0.39 ± 0.42 | |
| | | | | ACE inhibitor | 0.29 ± 0.44 | 0.29 |
| | | | | No ACE inhibitor | 0.35 ± 0.44 | |

[a]EBT indicates electron-beam tomography. ACE indicates angiotensin-converting enzyme.

### 6.4 Immunosuppression/Malignancy

As discussed previously, use of statins in recipients of solid organ transplants has shown promise in terms of reduced rates of rejection. Two major mechanisms for these beneficial effects have been proposed. First, statins inhibit interferon-δ-inducible MHC-II expression on macrophages and endothelial cells. Second, statins directly interfere with lymphocyte function-associated antigen-1 (LFA-1) binding to intracellular adhesion molecule-1. Both of these events impair activation of host T cells, and it is thought that this explains the reduced rates of rejection in transplant recipients. There have also been recent reports of promising results of statin use in patients with autoimmune diseases, such as rheumatologic conditions and multiple sclerosis. However, more data is needed before statins can be recommended as standard therapy in such conditions [50]. Statins have recently proven of use in modulation of inflammation-induced angiogenesis. This has spurred interest in their possible use in the treatment of malignancy. There have been some recent observational studies published that have shown reduced rates of diagnosis of cancer and fewer cancer-related deaths in statin users, but again, more data is needed.

### 6.5 Atrial Fibrillation

In the postoperative period, atrial fibrillation (AF) is thought to be initiated by triggered electrophysiologic abnormalities, which mostly occur in patients who have an abnormal atrial substrate [51]. High catecholamine

state [52] and inflammation [53] seen postoperatively is thought to play a key role. Increase in markers of inflammation, such as CRP and interleukin-6 after coronary artery bypass surgery, indicates an active inflammatory process after the procedure. Inflammatory changes have also been detected in the atrial biopsy specimens of patients with AF [54]. These findings suggest that AF may be induced by structural changes in the atria that are promoted by inflammation. Statins have modest anti-inflammatory actions, as indicated by decreased CRP levels with their administration [53, 55].

An observational study in 362 patients [56] showed postoperative AF was less frequent and its duration was shorter in statin group compared to nonstatin group ($p = 0.03$ and 0.0001, respectively). Another observational study of 25,268 patients from a registry of AF [57], 71.3% of patients had hyperlipidemia, and 66.8% were prescribed lipid-lowering drugs. Atrial fibrillation prevalence was 25.1% in patients taking lipid-lowering drugs compared with 32.6% in untreated hyperlipidemic patients and 32.8% in patients without hyperlipidemia ($p < 0.001$ for both comparisons). Lipid-lowering drug use was associated with reduced odds of AF, and this effect was larger than that of angiotensin-converting enzyme inhibitors/angiotensin receptor blockers or $\beta$-blockers. The beneficial impact of lipid-lowering drugs on atrial fibrillation risk was independent of their effects on the lipid profile.

## 7 CONCLUSION

The major advances in CHD diagnosis and treatment in the past half-century include the detection of thrombosis or a mechanism of acute coronary syndromes that leads to heart attacks and discovery of major risk factors that leads to progression of atherosclerosis. Next was the role of aspirin in prevention. The most eradicable risk factor is smoking cessation in the prevention of CHD. Most modifiable risk factor is LDL-cholesterol reduction that has been shown to cause regression of atherosclerosis and reduction in cardiac events. Statins play a major role in reducing LDL-cholesterol, hence reducing cardiac events in every study. Statins not only have their effects through LDL-cholesterol reduction, but have LDL-cholesterol-independent effects. The significance of the pleitropic effects is not well defined. Statins are, nonetheless, the only class of drugs that has been shown to consistently reduce CHD risk.

## 1 PLATELET PHYSIOLOGY IN CARDIOVASCULAR DISEASE

Platelets have a central role in the pathophysiology of atherosclerotic vascular disease. The interaction of platelets, atherosclerotic lesions, and the coagulation system is crucial in the transition from stable coronary artery disease (CAD) to unstable coronary syndromes such as unstable angina, non-ST-elevation myocardial infarction (NSTEMI), and ST-elevation infarction (STEMI) [1]. During acute coronary syndromes (ACS) and percutaneous coronary intervention (PCI), there is disruption of the natural protection provided by the endothelium with exposure to the subendothelial matrix. The hemodynamic and biochemical environment of circulating platelets changes, inducing the aggregation process. Binding of platelet surface receptors to von Willebrand's factor and collagen promotes platelet adhesion to the vessel wall, with subsequent platelet activation, granule secretion, and activation of the glycoprotein (GP) IIb/IIIa receptors. Irreversible platelet aggregation and additional recruitment of platelets eventually lead to occlusive thrombus generation. In addition to factors in the subendothelial matrix, thrombin is a primary agonist responsible for platelet activation. Following activation, arachidonic acid (AA) is released from membrane phospholipids and converted to thromboxane (Tx)A2 by cyclooxygenase (COX)-1 and Tx synthase. Secreted TxA2 binds to specific receptors on the platelet membrane surface activating surrounding platelets as a positive feedback mechanism. Once activated, adenosine diphosphate (ADP) is released from dense granules in platelets, which amplifies the platelet activation and recruitment phenomenon. The binding of ADP to the P2Y12 receptor triggers intracellular signaling pathways that result in GPIIb/IIIa receptor activation. In addition, platelet activation is characterized by the expression of surface adhesion molecules, such as P-selectin and CD40 ligand, and aggregation of platelets with leukocytes, which contributes to inflammation and amplification of thrombin generation [2, 3].

The binding of fibrinogen to the platelet surface via the calcium-dependent GPIIb/IIIa complex on the platelet surface is necessary for platelet aggregation induced by any agonist. The aggregation mechanism reflects the importance of a rapid and effective response to hemorrhage, which explains the high density of GPIIb/IIIa on the surface of platelets and the high concentration of circulating fibrinogen. The conformational change in GPIIb/IIIa results in its high affinity for the adhesive glycoprotein ligands and is the final common effector for platelet aggregation [4].

There is a well-known interindividual variation in platelet reactivity, which may contribute to the risk for thrombosis in certain individuals but protection in others. Enhanced platelet reactivity (i.e., platelet hyperreactivity) can prospectively identify subjects who are at risk for thrombotic events. The mechanisms responsible for the hyperreactivity are not well

understood, and it is not clear whether the underlying platelet hyperreactivity contributes to the thrombotic event or whether the stress of the acute event induces platelet activation [5]. Patients with hypertension, hyperlipidemia, diabetes, ACS, and during PCI have increased expression of platelet activation markers and greater platelet reactivity to agonists. Platelet hyperreactivity despite combined antiplatelet therapy has been linked to stent thrombosis, restenosis, inflammation, myocardial infarction (MI), and other ischemic events after PCI [2].

## 2 THERAPEUTIC TARGETS FOR PLATELET INHIBITION

Platelets have multiple functions that are complex and not limited to hemostasis. Understanding of platelet pathophysiology continues to grow with the recognition of the role platelets play in acute inflammation and in chronic inflammatory processes, such as atherosclerosis [6]. Platelets are primarily involved in thrombus formation, and the rationale for using antiplatelet agents is to decrease platelet activation, detain platelet procoagulant effect, block platelet-mediated inflammation, and favor platelet disaggregation to overall facilitate reperfusion of occluded arteries [2, 4].

Antagonism of the platelet activation/aggregation cascade is a crucial target in the management of cardiovascular patients, and the goal of antiplatelet therapy is to prevent or treat the formation of platelet-dependent thrombus [7]. No single signaling pathway involved in platelet activation is accountable for all thrombotic complications. Therefore, a single agent directed against a specific receptor or pathway is not expected to overcome all thrombotic complications [2].

Both the physiological and the pathological aggregation mechanism is the same, making it difficult to separate the therapeutic from the harmful effects of antiplatelet drugs. In clinical practice, a favorable balance between the beneficial and detrimental effects of antiplatelet therapy needs to be achieved by using these agents in those patients whose thrombotic risk outweighs their risk of bleeding complications and by administration of the minimal therapeutic dose possible [4].

## 3 THROMBOXANE A2 (TXA2) INHIBITORS

### 3.1 Aspirin

Aspirin is a synthetic compound with antipyretic, analgesic, anti-inflammatory, and antiplatelet properties that binds irreversibly to the active site of COX in platelets through acetylation. COX inactivation interferes with prostaglandin biosynthesis and results in reduced production of TxA2. Regular low doses of aspirin (e.g., 81 mg/day) will usually result in greater than 95% inhibition of TxA2 generation [8].

The use of aspirin is well established as a strategy for primary and secondary prevention of cardiovascular events in different populations [2] (see Table 1). The first trial to report a benefit in using aspirin among healthy males over 40 years of age was the Physicians' Health Study with a 44% decrease in first MI during 5 years of follow-up [9, 10]. A meta-analysis that included the six primary prevention trials using aspirin showed that this agent decreases the risk of total coronary heart disease, nonfatal MI, and total cardiovascular events, without affecting the incidence of stroke or cardiovascular mortality [11]. A gender-specific meta-analysis of randomized controlled trials confirmed that for women and men, aspirin therapy reduces the risk of cardiovascular events. However, aspirin significantly increased the risk of bleeding to a similar degree among both genders [12]. Therefore, the use of aspirin for primary prevention is controversial, but since the net benefit of aspirin is greater with increasing cardiovascular risk, the U.S. Preventive Services Task Force recommends aspirin for primary prevention in individuals who are at increased risk for coronary heart disease [13].

In healthy population, gender may play an important role in the response to aspirin. For both genders aspirin therapy reduces the risk of overall cardiovascular events with a similar increase in bleeding. However, the beneficial effect of aspirin is by reducing the risk of ischemic stroke in women and the risk of MI in men [12]. The Women's Health Study showed that among healthy women aspirin lowers the risk of stroke without affecting the risk of MI or death from cardiovascular causes [14].

Secondary prevention of cardiovascular events with chronic aspirin therapy has been demonstrated in patients with established atherosclerotic disease. The benefits of antiplatelet therapy were first demonstrated in studies designed to determine the effects of aspirin on cardiovascular risk in various high-risk patient groups. One example is ISIS 2 (International Study of Infarct Survival 2), which reported a reduction in vascular mortality in the setting of acute MI similar to the benefit achieved with fibrinolytic therapy using streptokinase [15], and the early survival advantages produced by fibrinolytic therapy and aspirin started in acute MI were maintained for at least 10 years [16]. This and other studies have set the foundation for recommending aspirin as the basis of antiplatelet therapy in all high cardiovascular risk patients unless contraindicated [17].

Laboratory aspirin resistance refers to less suppression of TxA2 production by aspirin than expected,

**TABLE 1 Aspirin and Clopidogrel in Clinical Trials**[a]

| Trial | Description | *n* | Main Conclusions | Reference |
|---|---|---|---|---|
| Women's Health Study | ASA every other day vs. placebo in primary prevention of CVD | 39876 | No reduction of primary endpoint (CV death, MI, or stroke) in overall population<br>Reduction of CV events in women older than 65 years<br>No benefit in CV death or MI<br>Reduction in risk of ischemic stroke<br>Nonsignificant increase in hemorrhagic stroke | 14 |
| STIMS | Long-term ticlopidine in patients with intermittent claudication | 687 | Reduction of MI, stroke, and transitory ischemic attacks<br>Reduction in mortality | 28 |
| STARS | Ticlopidine and ASA vs. ASA alone in patients with coronary stenting | 1965 | Reduction of stent thrombosis<br>Increased bleeding | 30, 31 |
| CLASSICS | Ticlopidine vs. clopidogrel (plus ASA) in patients after coronary stenting | 1020 | Clopidogrel group has reduced major peripheral or bleeding complications, neutropenia, thrombocytopenia, or early discontinuation of drug<br>Comparable efficacy with regard to cardiac events | 33 |
| CAPRIE | Clopidogrel vs. ASA in secondary prevention of CVD | 19185 | Clopidogrel group has reduced vascular death, MI, or stroke<br>No difference in safety (bleeding)<br>Clopidogrel has even greater efficacy in diabetic subgroup, prior CABG, prior MI, or ischemic stroke | 35–37, 173–175 |
| CURE | Clopidogrel and ASA vs. ASA for secondary prevention of CVD in patients with NSTEMI | 12562 | Dual therapy further decreases coronary events compared with ASA alone at 1 year | 39, 41, 176 |
| PCI-CURE and CREDO | Pretreatment with clopidogrel and ASA vs. ASA followed by long-term therapy in patients undergoing PCI | 4774 | Long-term dual-antiplatelet therapy beneficial in reducing ischemic events at 1 year<br>Reduced ischemic events at 28 days if 300 mg LD received more than 6 h before PCI | 42–44 |
| COMMIT | Clopidogrel in addition to ASA in patients with STEMI | 45852 | Adding clopidogrel to aspirin and other standard treatments (such as fibrinolytic therapy) reduces mortality and major vascular events | 45 |
| CLARITY-TIMI 28 | Clopidogrel vs. placebo in patients with STEMI and fibrinolytic therapy | 3491 | Addition of clopidogrel improves the patency rate of the infarct-related artery and reduces ischemic complications<br>Clopidogrel pretreatment reduces the incidence of cardiovascular death or ischemic complications both before and after PCI<br>Benefit seen in the overall trial population in the risk of cardiovascular death, recurrent MI, or recurrent ischemia requiring urgent revascularization at 30 days—among patients undergoing CABG, there is a trend toward reduction of risk<br>No excess bleeding in the clopidogrel group<br>Clopidogrel appears to improve late coronary patency and clinical outcomes by preventing reocclusion of open arteries rather than by facilitating early reperfusion | 46, 47, 177, 178 |

(*Continued*)

**TABLE 1** ***Continued***

| Trial | Description | *n* | Main Conclusions | Reference |
|---|---|---|---|---|
| CHARISMA | Clopidogrel and ASA combination therapy in symptomatic (prior CVD) and asymptomatic (no prior CVD) populations | 15603 | Excess of all-cause mortality, and early and sustained risk of severe bleeding within the asymptomatic group<br>No significant effect on cardiovascular mortality in the symptomatic group<br>Do not support use of dual-antiplatelet therapy with clopidogrel and ASA in primary prevention population<br>Patients with documented prior MI, ischemic stroke, or symptomatic PAD benefit from dual antiplatelet therapy | 48, 179, 180 |
| ALBION | Clopidogrel LD 300, 600, or 900 mg plus ASA in low-to-moderate risk patients with NSTEMI | 103 | Clopidogrel LD greater than 300 mg provide a faster onset of action and greater reductions in platelet activation during the first 24 h<br>900-mg LD may induce greater antiplatelet effect than 600 mg, when compared with the standard 300-mg regimen | 51 |
| ISAR-CHOICE | Clopidogrel 300, 600, or 900 mg | 60 | Greater platelet inhibition with 600 and 900 mg LD<br>Similar platelet inhibition and active metabolite levels with 600 and 900 mg LD (there may be saturable absorption and/or metabolism) | 181 |
| ARMYDA 2 | Clopidogrel LD 300 or 600 mg in patients before PCI | 255 | Lower rates of periprocedural MI with 600 mg LD<br>No excess bleeding in the higher LD group | 49 |
| CURRENT OASIS 7 | Clopidogrel higher LD and early MD in patients with unstable angina and NSTEMI with planned early invasive therapy | NA | Ongoing (no results available) | NA |
| OPTIMUS | Clopidogrel 150 mg MD compared with 75 mg MD in patients with DM with suboptimal response to standard dose | 40 | Greater platelet inhibition with 150 mg MD<br>Persistent variability of response and presence of hyporesponsiveness<br>No clinical outcomes | 167 |
| ISAR-CHOICE 2 | Clopidogrel 150 mg MD compared with 75 mg MD in patients after PCI | 60 | Greater platelet inhibition with 150 mg MD<br>Persistent variability of response and presence of hyporesponsiveness<br>No clinical outcomes | 182 |

[a] *n*, number of subjects in trial; ASA, aspirin; CV, cardiovascular; CVD, cardiovascular disease; STEMI, ST-elevation myocardial infarction; LD, loading dose; MD, maintenance dose; DM, diabetes mellitus; MI, myocardial infarct; CABG, coronary artery bypass graft; NA, not available.

which is associated to the lack of an anticipated effect of the drug on a laboratory measure of platelet function [18]. Several COX-specific and nonspecific assays have shown a prevalence of aspirin nonresponse between less than 1% and up to 54% in different populations with cardiovascular disease [2]. There appears to be a clinical relevance of response variability to antiplatelet treatment since recent meta-analysis show that patients who are classified as nonresponsive to aspirin are at greater long-term risk of clinically important cardiovascular morbidity when compared to individuals who are sensitive to aspirin [19, 20]. Many tests have been used to assess aspirin resistance (e.g., arachidonic-acid- and ADP-induced light transmission aggregometry, VerifyNow aspirin assay, thromboelastography with platelet mapping, flow cytometry using arachidonic acid

stimulation, and serum and urinary thromboxane among others). Tests are ideally performed before and after drug administration. Even when some of these tests have been reported to be predictive of adverse clinical events, the majority of these studies are small and statistically underpowered to determine if each test can reliably predict the small number of adverse outcomes that were observed [8]. The assessment of aspirin nonresponse is highly dependent on the assay used and higher estimates of nonresponse are observed with methods that do not use arachidonic acid as the stimulus [21].

Several potential mechanisms could be considered responsible for the variability in aspirin response, such as decreased bioavailability, interference with other drugs, accelerated platelet turnover, and COX-1 variants that may be less responsive to aspirin inhibition [22]. There are also several potential reasons why aspirin may not prevent recurrent vascular events. Noncompliance has been reported in up to 60% of patients with cardiovascular disease; comorbidities like hypercholesterolemia, diabetes mellitus, or unstable angina and smoking may stimulate the production of isoprostanes, which may enhance the response of platelets to other agonists through COX-independent TxA2 biosynthesis; common risk factors such as hypercholesterolemia may affect modulation of thrombin in response to aspirin and increased oxidative stress associated with hyperglycemia may limit the effect of antiplatelet therapy [23].

There is controversy about whether higher doses of aspirin reduce hyporesponsiveness since higher doses of aspirin (650–1500 mg/day) are not superior compared to lower doses (50–100 mg/day) in the reduction in the risk of vascular death, MI, or stroke [23, 24].

### 3.2 Other TxA2 Inhibitors

There are other drugs that also target the TxA2 pathway in platelets, but its use has been more limited. For example, the TxA2 receptor and prostaglandin endoperoxide receptor antagonist ridogrel in RAPT (Ridogrel versus Aspirin Patency Trial) did not have any apparent advantages over aspirin in patients with acute MI [25].

There are other compounds under investigation. The nitric-oxide-releasing aspirin, NCX-4016, has shown beneficial effects in experimental models of restenosis and diabetic vein grafts. The TxA2 receptor antagonist S18886 reversibly inhibits both TxA2 and other eicosanoids not affected by aspirin. In animal models, this compound prevented atherogenesis and caused plaque regression, and single dose in patients with CAD improved endothelial function [26].

## 4 ADP RECEPTOR ANTAGONISTS: THIENOPYRIDINES

Platelet function depends on a complex network of signaling pathways that lead to the common goal of platelet activation and aggregation. Aspirin acts by blocking COX and thereby reducing levels of TxA2, but it does not prevent platelet activation by TxA2-independent pathways. This sets the rationale for combining aspirin with other antiplatelet agents that act by blocking complementary mechanisms [17]. There are studies performed prior to the appearance of clopidogrel that demonstrate a synergistic benefit of thienopyridine and aspirin therapy. These studies confirm the superiority of dual antiplatelet therapy over aspirin alone or aspirin with warfarin in preventing stent thrombosis.

### 4.1 Ticlopidine

Ticlopidine is a prodrug and needs to be metabolized through cytochrome P450 in the liver to an active metabolite that specifically and irreversibly blocks the platelet ADP receptor. It is the first P2Y12 antagonist approved by the Food and Drug Administration (FDA) and is given orally twice a day.

Results from numerous large studies showed that patients with prior transient ischemic attacks or stroke, and those with peripheral arterial disease or ischemic heart disease, benefit from using ticlopidine. Ticlopidine reduced the incidence of stroke, MI, or vascular death and was superior to placebo and aspirin in patients with recent stroke, transient ischemic attacks, or intermittent claudication. Ticlopidine also appeared to reduce anginal pain [27]. For example, the Swedish Ticlopidine Multicentre Study (STIMS) reported that morbidity and mortality from cardio- and cerebrovascular disease in patients with intermittent claudication could be reduced by long-term treatment with ticlopidine [28], and the risk of nonfatal myocardial infarction was reduced in patients with unstable angina treated with ticlopidine [29]. The STARS (Stent Anti-thrombotic Regimen Study) study showed that treatment with aspirin and ticlopidine compared with aspirin alone and a combination of aspirin and warfarin resulted in a lower rate of stent thrombosis, although there were more hemorrhagic complications than with aspirin alone [30]. The STARS registry showed that the acute clinical results of suboptimal stent deployment was acceptable when treatment with ticlopidine was used, even when it was not quite as good as with optimal stenting and similar drug therapy [31].

In large clinical trials, patients treated with ticlopidine had a higher incidence of adverse effects than placebo, but most did not require withdrawal of

treatment. Gastrointestinal symptoms (particularly diarrhea) were common, and other adverse effects were skin rash, hemorrhagic disorders, and hematological effects. These required careful monitoring of patients during the initial weeks of therapy [27]. Clopidogrel is preferred because of the adverse event profile for ticlopidine [2]. In the United States and other countries, ticlopidine has been largely replaced in clinical practice by clopidogrel, which is given in a more convenient daily dose and has a better safety and tolerability profile (e.g., less neutropenia and lower incidence of thrombotic thrombocytopenic purpura) [7].

### 4.2 Clopidogrel

Clopidogrel is also a prodrug that is metabolized by cytochrome P450 in the liver to an active metabolite that specifically and irreversibly blocks the platelet ADP receptor P2Y12 [8]. When no loading dose is administered, 75 mg of daily clopidogrel causes some level of platelet inhibition as early as 2 h after treatment initiation, but maximal inhibition is not achieved for 3–7 days. This delay can be considerably decreased by using a standard 300-mg loading dose. The time to achieve the maximal effect is between 2 and 24 h after administration of the loading dose. With a 600-mg loading dose, full antiplatelet effect takes 2–4 h to build up. A higher dose of 900 mg causes marginal increases in the magnitude and speed of platelet inhibition with no significant differences when compared to 600 mg [17].

In patients who have undergone PCI, a maintenance dose of 75 mg daily clopidogrel should be given for at least 1 month after bare metal stent implantation unless the patient is at increased risk for bleeding, or 3–6 months after drug eluting stent implantation, and ideally up to 12 months in patients who are not at high risk of bleeding [32]. The active clopidogrel metabolite is pharmacodynamically similar to aspirin, and it causes inhibition of platelet function by repeated daily administration of low doses. Platelet function returns to normal 7 days after the last dose. The cumulative inhibitory effect and the slow rate of recovery of platelet activity are consistent with permanent defects in platelet proteins, which can only be replaced as a function of platelet turnover. Therefore, only once daily administration is needed despite its short half-life of 8 h in human circulation [4].

There is abundant clinical evidence that supports the use of clopidogrel in the treatment of several cardiovascular conditions, especially acute coronary syndromes [26] (see Table 1).

CLASSICS (Clopidogrel Aspirin Stent International Cooperative Study) showed that the tolerability of clopidogrel was superior to that of ticlopidine, while having comparable efficacy with regard to cardiac events after successful coronary stenting [33]. A meta-analysis suggested that using clopidogrel decreases major cardiac events and mortality 30 days after coronary stenting as compared to ticlopidine [34]. Therefore, clopidogrel therapy has mainly replaced ticlopidine in PCI [26].

Based on results from CAPRIE (Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events) showing that clopidogrel was marginally superior to aspirin for secondary prevention in patients with recent MI, ischemic stroke, or peripheral arterial disease (PAD) [35–37], clopidogrel has become the alternative antiplatelet agent for patients with aspirin intolerance [26]. However, because there was a small effect size and the statistical significance achieved in a large sample was marginal, the U.S. FDA did not grant a superiority claim over aspirin but assigned a claim of efficacy relative to placebo. The overall safety and tolerability profile of clopidogrel appeared to be as good as that of medium-dose aspirin [38].

CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Events) confirmed that clopidogrel was effective in the acute management of NSTEMI [39] regardless of patient risk profile [40], and the therapeutic benefit was sustained after 1 year [41]. However, an increased bleeding risk was observed in this study in patients receiving clopidogrel. PCI-CURE analyzed the data from patients with non-ST-elevation acute coronary syndrome undergoing PCI in the CURE study and showed that pretreatment and long-term administration of clopidogrel in patients that undergo PCI was advantageous [42]. CREDO (Clopidogrel for the Reduction of Events During Observation) suggested that long-term clopidogrel therapy following PCI significantly reduced the risk of adverse ischemic events. A loading dose of clopidogrel given at least 3 h before the procedure did not reduce events at 28 days, but subgroup analyses suggested that longer intervals between the loading dose and the PCI may reduce events. The risk of major bleeding increased but not significantly with the use of clopidogrel [43, 44].

Clopidogrel in addition to standard therapy for the management of acute MI provided further reduction in mortality and ischemic events, as shown in COMMIT (Clopidogrel and Metoprolol in Myocardial Infarction Trial) [45] and CLARITY-TIMI 28 (Clopidogrel as Adjunctive Reperfusion Therapy—Thrombolysis in Myocardial Infarction 28), supporting the early use of clopidogrel in STEMI and the strategy of routine clopidogrel pretreatment in patients undergoing PCI [46, 47]. The synergistic benefits of combination therapy seen with clopidogrel and aspirin in acute coronary syndromes and after PCI led to the evaluation of long-term dual antiplatelet treatment in high-risk patients for primary and secondary prevention. The CHARISMA

(Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization Management and Avoidance) trial showed no benefit with an increase in moderate bleeding in the primary prevention subgroup, but there was reduction of death, MI, and stroke, the primary endpoint of the study, in patients with a prior MI, stroke, or symptomatic PAD [48]. Results suggested there was a relationship between treatment benefit and underlying cardiovascular risk. In high-risk patients with ACS or in those undergoing PCI (both conditions characterized by platelet hyperreactivity), the efficacy benefit outweighed the bleeding risk. On the contrary, bleeding risk exceeded benefit in low-risk patients who were not undergoing PCI [38].

Results from ARMYDA 2 (Anti-platelet Therapy for Reduction of Myocardial Damage during Angioplasty) favored the use of a higher loading dose of 600 mg of clopidogrel in patients undergoing PCI with a benefit in clinical outcomes [49]. A recent meta-analysis showed that clopidogrel loading dose greater than 300 mg reduced early ischemic events in patients scheduled for PCI with a possibility that the greater the underlying risk, the greater the favorable impact of a high loading dose [50]. The ongoing CURRENT-OASIS 7 (Clopidogrel Optimal Loading Dose Usage to Reduce Recurrent Events/Optimal Anti-platelet Strategy for Interventions 7) trial will evaluate the clinical effect of higher loading and maintenance dose of clopidogrel in patients with unstable angina and NSTEMI [26].

Variability of response to clopidogrel has led to changes in clinical practice and use of higher doses of clopidogrel, especially in patients undergoing PCI. The evidence that higher dose of clopidogrel maintenance therapy provides more effective platelet inhibition is supported by the ALBION (Assessment of the Best Loading Dose of Clopidogrel to Blunt Platelet Activation, Inflammation and Ongoing Necrosis) study. In this trial, greater loading doses were associated with significantly greater platelet inhibition when compared with the standard 300-mg loading dose. There was a dose–effect relationship for onset of action, maximal plateau, platelet inhibition at 24 h, and rates of low inhibition of platelet aggregation (less than 10% at 6 h). Similar but nonsignificant trends were observed for troponin release and major adverse cardiac events. Bleeding rates were similar among groups. The investigators concluded that in low- to moderate-risk patients with NSTEMI, clopidogrel loading doses greater than 300 mg provide a faster onset of action, a higher inhibition of platelet aggregation, and greater reductions in platelet activation during the first 24 h [51].

Current PCI guidelines provide a class IIb recommendation for patients in whom subacute stent thrombosis may be catastrophic or lethal to consider platelet aggregation studies and increasing the daily maintenance dose of clopidogrel from 75 to 150 mg if less than 50% inhibition of platelet aggregation is demonstrated [52].

All these studies indicate that clopidogrel plus aspirin is better in high-risk patients, such as those with NSTEMI, STEMI, and stenting, than aspirin alone. Long-term benefit appears to be associated with reductions in nonfatal MI, with little impact on death or stroke, while major bleeding complications are increased.

In patients with stable cardiovascular disease there seems to be no long-term benefit but an increased bleeding risk associated with chronic use of clopidogrel, and therefore, it is not recommended in such patients. However, in high-risk patients with NSTEMI and at low risk for bleeding, treatment with clopidogrel should be given for at least 1 month and up to 9 months. In patients with STEMI and fibrinolytic treatment at least 1 month of treatment is recommended, and there are no direct studies in patients with primary PCI [38].

The optimal timing and dose of clopidogrel pretreatment before PCI has not been established. Even though a nonrandomized subgroup analysis of CURE reflected that pretreatment was associated with favorable outcomes [38], in ISAR-REACT (Intracoronary Stenting and Antithrombotic Regimen—Rapid Early Action for Coronary Treatment), there were no treatment differences in low- to intermediate-risk patients receiving a 600-mg clopidogrel loading dose 2–3 h before PCI when compared to those receiving the same loading dose 12 h before the procedure [53]. The American College of Cardiology (ACC)/American Heart Association (AHA) guidelines recommend administration of 300 mg of clopidogrel at least 6 h before elective PCI, while the European Society of Cardiology guidelines recommend 600 mg clopidogrel at least 2–6 h before PCI. Further clinical trials are needed regarding dose, time course of pretreatment, and associated benefit of clopidogrel in the management of ACS patients and those undergoing elective PCI.

Despite the clinical benefit achieved with the adjunct of clopidogrel in patients with ACS and undergoing PCI, a considerable number of patients continue to have cardiovascular events. This has been attributed in part to the fact that some individuals may have poor response to clopidogrel treatment and have enhanced platelet reactivity, which is pivotal for the development of atherothrombotic complications [54]. Currently, no definition of true clopidogrel nonresponse has been universally accepted and different researchers have used various platelet function tests and assigned a variety of empiric cut-off values in the laboratory to define it [55].

Laboratory responses to P2Y12 inhibitors are largely based upon monitoring ADP-stimulated responses,

ideally before and after drug administration [8]. Maximum platelet aggregation induced by ADP and measured by light transmission aggregometry (LTA) is the most commonly used laboratory method to evaluate responsiveness to clopidogrel and is considered the gold standard [2]. LTA using 5 or 20 μmol/L ADP has been used to arbitrarily classify patients based upon the change in aggregation (delta aggregation) at baseline and after drug administration. Nonresponders have been defined with a delta aggregation of less than 10%. Several studies show that there is substantial variation in patient response to clopidogrel and up to 30% of patients may be nonresponders [8]. The phosphorylation state of vasodilator-stimulated phosphoprotein (VASP) can be measured by flow cytometry and is a specific marker of residual P2Y12 receptor activity in patients treated with a P2Y12 inhibitor, such as clopidogrel [8].

Some studies in patients undergoing percutaneous revascularization have suggested a relation between high posttreatment platelet reactivity, clopidogrel nonresponsiveness, and increased ischemic events, including stent thrombosis [56]. However, justification of clopidogrel nonresponse based on clinical outcomes can be misleading. A number of studies have shown that patients that do not respond to clopidogrel are at an increased risk of vascular events, especially subacute stent thrombosis (SAT), but the risk of SAT is 1–2%, while between 5 and 60% of patients are found to be clopidogrel nonresponders [55]. There are limited data that link clopidogrel nonresponsiveness to subsequent thrombotic events. Several small studies have suggested that patients with higher residual platelet reactivity after the initiation of clopidogrel therapy have a greater frequency of subsequent major adverse cardiovascular events. Higher doses of clopidogrel or other antiplatelet agents may, therefore, be beneficial in these patients [24, 57]. The PREPARE (Platelet Reactivity in Patients and Recurrent Events) study showed that patients with recurrent ischemic events despite dual antiplatelet therapy after elective stenting had higher platelet reactivity than patients without ischemic events [58]. Higher levels of platelet aggregation, active GPIIb/IIIa expression, and the P2Y12 reactivity ratio measured by VASP phosphorylation were reported in patients with stent thrombosis in the CREST (Clopidogrel Effect on Platelet Reactivity in Patients with Stent Thrombosis) study, suggesting inadequate P2Y12 receptor inhibition [59]. In CLEAR PLATELETS (Clopidogrel Loading with Eptifibatide to Arrest PLATELET Reactivity Study) a higher loading dose of clopidogrel in patients undergoing elective PCI achieved greater early platelet inhibition compared to the standard dose, and this seemed to be related with a decrease in myocardial necrosis and inflammation markers [60, 61]. Those patients who were less responsive to aspirin seemed also more frequently hyporesponsive to clopidogrel [62, 63], but further evidence is needed since other studies do not report an overlap in hyporesponsiveness with these agents [24].

Clopidogrel nonresponsiveness seems to depend on dose, and higher loading dose is associated with a narrower response profile. A higher loading dose with 600 mg of clopidogrel accelerates the onset of the antiplatelet effect and enhances the magnitude of platelet inhibition when compared to either no loading dose or the standard 300-mg dose. The higher dose also reduces the prevalence of nonresponse to clopidogrel, but there is limited clinical-trial-based evidence to support its safety and greater efficacy [57]. For example, in ARMYDA 2 it was not determined if subjects treated with 600 mg had a lower event rate because the higher dose was more rapidly acting or because it caused greater platelet inhibition and less hyporesponsiveness compared with the standard loading dose [24]. A small, prospective randomized trial presented at the American College of Cardiology Scientific Sessions 2008/i2 Summit-SCAI Annual Meeting suggests that titration of the clopidogrel dose upward based on the results of a platelet reactivity test that measures VASP can reduce the risk of clinical events over the short term.

In contrast, MATCH (Management of Atherothrombosis with Clopidogrel in High-Risk Patients) and CHARISMA showed that the lack of efficacy in patients after stroke and for primary prevention was not caused by low response to clopidogrel, and significant increases in bleeding events suggested adequate or even excessive platelet inhibition with clopidogrel [64].

The mechanisms leading to variability in clopidogrel responsiveness are not fully elucidated and, similarly to aspirin, are likely multifactorial. High baseline platelet reactivity, poor compliance, inappropriate dosing, upregulation of the P2Y12 pathway, and upregulation of P2Y12-independent pathways, differences in individual absorption and/or metabolism of clopidogrel as well as different levels of its active metabolite may all contribute to variations in the level of antiplatelet effects of clopidogrel seen in different patients. For example, drugs that are substrates or inhibit the cytochrome P450 (CYP) isoenzyme 3A4 can potentially interfere with the conversion of clopidogrel into its active metabolite, leading to reduced antiplatelet effects, and genetic polymorphisms of this and other CYP enzymes have been shown to modulate individual response to clopidogrel [54].

Before a patient is considered as a clopidogrel nonresponder, nonplatelet factors should be evaluated, such

as treatment compliance (about 20% of patients are noncompliant with treatment), suboptimal stent deployment (which can increase the risk of SAT despite adequate anticoagulation), drug–drug interactions, or other prothrombotic states [55]. The current therapeutic alternative for treatment of patients with poor clopidogrel response remains limited. Response variability to clopidogrel has served as the basis for the development of new P2Y12 inhibitors with superior pharmacodynamic profiles (e.g., prasugrel and AZD 6140) [56]. Only a well-designed, large, randomized study with a hard outcome or survival endpoint, supported by serial platelet assessment and measurement of clopidogrel metabolites, will determine if clopidogrel nonresponse is a real hazard as suggested by platelet biomarkers and function tests [64].

## 5 GLYCOPROTEIN IIB/IIIA INHIBITORS

Given the redundancy of signaling pathways that lead to platelet aggregation, the clinical efficacy of aspirin, ticlopidine, and clopidogrel is only partial. These drugs inhibit TXA2-mediated or ADP-mediated platelet aggregation but leave the activity induced by other platelet agonists (e.g., thrombin) mostly unchanged. The expression of active GPIIb/IIIa on the platelet surface is the final common pathway of platelet aggregation regardless of the initiating stimulus. Therefore, this molecule became a main target of antiplatelet drugs. GPIIb/IIIa receptors blockade appears as a particularly desirable therapeutic strategy because: (1) monoclonal antibodies to GPIIb/IIIa are more potent inhibitors of platelet function than aspirin; (2) GPIIb/IIIa is platelet specific; (3) GPIIb/IIIa antagonism leaves platelet adhesion largely intact, contributing to hemostasis without causing thrombotic damage; and (4) the hemorrhagic diathesis produced by the inherited deficiency of GPIIb/IIIa receptors (Glanzmann thrombasthenia) only rarely produces spontaneous brain hemorrhage, one of the most feared complications of antiplatelet therapy [4].

Abciximab is a monoclonal antibody that has high affinity and a slow rate of dissociation from GPIIb/IIIa, and the small molecules eptifibatide and tirofiban have a much more rapid rate of dissociation, with an off time of 10–15 s. The circulating pool of abciximab is predominantly associated with platelets, while maintenance of a constant concentration of tirofiban and eptifibatide in the blood is needed to achieve and sustain their inhibitory effects. The GPIIb/IIIa affinity of abciximab and tirofiban is greater than that of eptifibatide, and greater concentration of eptifibatide in blood is required for effective inhibition of the binding of fibrinogen to the activated conformer of GPIIb/IIIa [65]. There is clinical evidence that supports the use of GPIIb/IIIa inhibitors in the treatment of several cardiovascular conditions (see Table 2).

### 5.1 Abciximab

Abciximab is a Fab fragment of the 7E3 antibody that has high affinity and a slow rate of dissociation from GPIIb/IIIa. Abciximab has a plasma half-life of about 10 min, with a second-phase half-life of about 30 min. However, its effects on platelet function can be seen for up to 48 h after the infusion has been stopped [65].

In the 1990s, the placebo-controlled trials EPIC (Evaluation of c7E3 for Prevention of Ischemic Complications) [66, 67], EPILOG (Evaluation of PTCA to Improve Long-Term Outcome with Abciximab GPIIb-IIIa Blockade) [68–71], and EPISTENT (Evaluation of Platelet Inhibition in Stenting) [72] included over 7000 subjects from a broad group of PCI patients and consistently documented the efficacy of abciximab in reducing periprocedural ischemic complications of death, MI, and the need for repeat revascularization, with sustained benefits for at least 3 years of follow-up.

The CAPTURE (C7E3 Anti-Platelet Therapy in Unstable Refractory Angina) trial confirmed that in patients with refractory angina undergoing PCI, abciximab reduced the risk of death, MI, or repeat revascularization at 30 days. This benefit was absent at 6 months, probably due to differences in dosing regimes when compared to previous trials with abciximab where the drug was continued for 12 h rather than only 1 h after the procedure. On the other hand, CAPTURE showed that use of abciximab for 18–24 h prior to PCI decreased the incidence of MI before the procedure, suggesting that patients with unstable angina and non-Q-wave MI can benefit from GPIIb/IIIa antagonism regardless of PCI [73, 74]. This was addressed in GUSTO IV (Global Use of Strategies to Open Occluded Coronary Arteries IV), which evaluated abciximab used in medical management of ACS (excluding patients with ST-segment elevation MI) [75, 76]. The absence of any efficacy was not anticipated since previous trials using small molecules, such as PURSUIT (Platelet IIb-IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy) [77, 78], PRISM (Platelet Receptor Inhibition in Ischemic Syndrome Management) [79], and PRISM-Plus (Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Angina) [80] showed benefit in this setting. The practical outcome of these trials was a more limited use of abciximab in patients scheduled for PCI and a restricted application in the medical management of ACS.

**TABLE 2 GPIIb/IIIa Inhibitors in Clinical Trials[a]**

| Trial | Description | *n* | Main Conclusions | Reference |
|---|---|---|---|---|
| EPIC | Abciximab vs. placebo for prevention of ischemic complications in high-risk PCI (with bailout stenting) | 2099 | Reduced risk of death, MI, or recurrent ischemia at 30 days, 6 months, and 3 years, but associated with more major and minor bleeding<br>Dose-dependent effect<br>Reduced incidence of clinical restenosis at 6 months | 66, 67 |
| EPILOG | Abciximab vs. placebo for prevention of ischemic complications in PCI (all patients, regardless of risk, with bailout stenting) | 2792 | Reduced risk of death, MI, or recurrent ischemia at 30 days and 6 months<br>No increase in bleeding risk with more conservative use of heparin during procedure, no postprocedure heparin and early sheath removal<br>No reduced incidence of clinical restenosis at 6 months | 68–71 |
| EPISTENT | Abciximab vs. placebo for prevention of ischemic complications in PCI (all patients, regardless of risk, with routine stenting) | 2399 | Periprocedural benefits with abciximab (death and MI) are independent of stenting<br>Abciximab + stent complimentary long-term clinical benefits<br>Overall stenting offers best protection against clinical restenosis<br>In diabetics addition of abciximab further reduces risk of restenosis | 72 |
| IMPACT II | Eptifibatide vs. placebo for prevention of ischemic complications in PCI | 4010 | Reduced risk of death, MI, or recurrent ischemia at 30 days but not 6 months<br>No dose-dependent effect<br>Only 30–50% inhibition of platelet aggregation (i.e., suboptimal dosing) | 99 |
| ESPRIT | Higher dose eptifibatide vs. placebo for prevention of ischemic complications in PCI (all patients, regardless of risk, with routine stenting) | 2604 | Reduced risk of death, MI, or recurrent ischemia at 30 days and 6 months<br>Increase in major bleeding risk despite conservative use of heparin<br>Greater than 90% inhibition of platelet aggregation | 100–103 |
| RESTORE | Tirofiban vs. placebo for prevention of ischemic complications in patients with ACS and elective PCI | 2139 | Reduced risk of death, MI, or recurrent ischemia at 30 days but not 6 months<br>No increase in bleeding risk<br>No reduced incidence of angiographic restenosis at 6 months | 104 |
| TARGET | Tirofiban vs. abciximab for prevention of ischemic complications in PCI | 4809 | Superiority of abciximab over tirofiban at 30 days with no difference in rates of major bleeding<br>Similar level of protection against the composite of death, myocardial infarction, and any target-vessel revascularization at 6 months<br>Similar level of survival benefit at 1 year | 105–107 |
| CAPTURE | Abciximab vs. placebo for prevention of ischemic complications in PCI to treat unstable refractory angina | 1265 | Reduced risk of death, MI, or repeat revascularization at 30 days but not 6 months<br>Reduced risk of MI prior to PCI with pretreatment | 73, 74 |

**TABLE 2** ***Continued***

| Trial | Description | *n* | Main Conclusions | Reference |
|---|---|---|---|---|
| PURSUIT | Eptifibatide vs. placebo for prevention of ischemic complications in medical management of ACS | 10498 | Reduced risk of death and MI at 30 days an 6 months<br>Most of benefit is derived from a decrease in non-Q-wave MI<br>Patients who subsequently underwent PCI were subgroup with most pronounced benefit | 77, 78 |
| PRISM | Tirofiban vs. placebo for prevention of ischemic complications in medical management of ACS | 3232 | Reduced risk of death, MI, or refractory ischemia at 48 h but not 30 days | 79 |
| PRISM-Plus | Tirofiban vs. placebo for prevention of ischemic complications in medical management of ACS | 1915 | Reduced risk of death, MI, or refractory ischemia in tirofiban with heparin treatment arm at 7 days, 30 days, and 6 months<br>Patients who subsequently underwent PCI were subgroup with most pronounced benefit<br>Increased risk of death in tirofiban only treatment arm at 7 days | 80 |
| GUSTO IV | Abciximab vs. placebo for prevention of ischemic complications in medical management of ACS | 7800 | Lack of efficacy<br>No survival benefit at 1 year<br>In patients with low cardiac troponin or elevated C-reactive protein, abciximab was associated with excess mortality | 75, 76 |
| RAPPORT | Adjunctive therapy with abciximab in primary PCI | 483 | Reduced risk of death, reinfarction, or target vessel revascularization at 30 days | 81 |
| ISAR-2, ACE, and ADMIRAL | Adjunctive therapy with abciximab in primary stenting | | Reduced risk of death, reinfarction, or target vessel revascularization at 30 days, 6 months, 1 year and up to 3 years | 82–87 |
| CADILLAC | Adjunctive therapy with abciximab in primary PCI or stenting | 2082 | In primary PCI reduced risk of death, reinfarction, target vessel revascularization, or stroke at 30 days<br>In primary stenting no benefit | 88, 89 |
| ASSENT III and GUSTO V | Abciximab and half-dose fibrinolytics vs. full-dose fibrinolytics | Over 22,000 | Decreased reinfarction rate<br>Increased major bleeding<br>No overall difference in mortality at 1 year | 90–93 |
| ISAR-REACT | Pretreatment with clopidogrel (LD 600 mg) in PCI with routine use of abciximab | 2159 | No additional benefit in reduction of death, MI, or urgent target vessel revascularization at 30 days | 53 |
| FINESSE | Half-dose reteplase/ abciximab vs. abciximab alone in STEMI patients undergoing PCI | 2453 | Improved coronary patency before PCI<br>No significant benefit in short-term outcomes: no differences between<br>treatment arms for the primary composite endpoint at 90 days of all-cause mortality, readmission for heart failure, ventricular fibrillation, or cardiogenic<br>shock<br>No differences in all-cause mortality, complications of MI, or any of the independent components<br>Major and minor bleedings more common in the combination strategy as compared with primary PCI and as compared with the abciximab-only group | 94, 95 |

**TABLE 2** ***Continued***

| Trial | Description | *n* | Main Conclusions | Reference |
|---|---|---|---|---|
| EXCITE, SYMPHONY, OPUS-TIMI 16, FROST | Oral IIb/IIIa (xemilofiban, sibrafiban, orbofiban, or lefradiban) in patients with ACS or undergoing PCI | Over 27,000 | No increased efficacy<br>Increased bleeding events<br>Increased mortality or MI | 108, 110 |
| 2nd SYMPHONY | Combination therapy with low-dose sibrafiban and aspirin vs. aspirin or high-dose sibrafiban alone in patients with ACS | 6637 | Terminated early because of results from SYMPHONY<br>Long-term use of sibrafiban associated with increased bleeding complications | 110 |
| BRAVO | Lotrafiban in patients with recent MI, unstable angina, transient ischemic attack, or ischemic stroke, or peripheral vascular disease combined with either cardiovascular or cerebrovascular disease | NA | Terminated early because excess mortality at interim analysis | 110, 183 |

[a]*n*, number of subjects in trial; ASA, aspirin; CV, cardiovascular; CVD, cardiovascular disease; STEMI, ST-elevation myocardial infarction; LD, loading dose; MD, maintenance dose; DM, diabetes mellitus; MI, myocardial infarct; CABG, coronary artery bypass graft; NA, not available.

The benefits of abciximab in primary PCI and primary stenting were confirmed in RAPPORT (ReoPro and Primary PTCA Organization and Randomized Trial) [81] and ISAR 2 (Intracoronary Stenting and Antithrombotic Regimen 2), ACE (Abciximab and Carbostent Evaluation), and ADMIRAL (Abciximab before Direct Angioplasty and Stenting in Myocardial Infarction Regarding Acute and Long-term Follow-up) [82–87]. In contrast, CADILLAC (Controlled Abciximab and Device Investigation to Lower Late Angiographic Complications) showed a benefit of adjunctive abciximab therapy with primary PCI, but none with primary stenting, which may have been associated with thienopyridine use prior to catheterization [88, 89].

ASSENT 3 (Assessment of the Safety of a New Thrombolytic 3) and GUSTO V (Global Use of Strategies to Open Occluded Coronary Arteries V) showed that abciximab used with fibrinolytics did not add benefit to pharmacological reperfusion therapy [90–93]. FINESSE (Facilitated Intervention with Enhanced Reperfusion Speed to Stop Events) showed there was improved coronary patency before PCI with half-dose reteplase/abciximab in STEMI patients, however, without significantly improving short-term outcome [94, 95]. This provided further insight into the role of combination of GPIIb/IIIa inhibitor and thrombolytics in acute MI.

In patients at low to intermediate risk who underwent elective PCI after pretreatment with a high loading dose of clopidogrel, abciximab was not associated with a clinical benefit within the first 30 days [96]. However, ISAR-REACT 2 showed in high-risk patients with NSTEMI undergoing a PCI after pretreatment with 600 mg clopidogrel that adverse events occured less frequently with abciximab, the early benefit was maintained at 1 year after administration, but the benefits provided by abciximab appeared to be confined to patients presenting with an elevated troponin level [97, 98]. Therefore, adjunctive use of clopidogrel and a GPIIb/IIIa inhibitor was effective and safe in high-risk patients with ACS, while pretreatment with a higher loading dose of clopidogrel may be an acceptable alternative to GPIIb/IIIa inhibition in low-risk patients [38]. However, it has been suggested that the use of the GPIIb/IIIa inhibitor abciximab in acute STEMI patients undergoing PCI after pretreatment with a 600-mg loading dose of clopidogrel does not reduce infarct size, according to the Bavarian Reperfusion Alternatives Evaluation-3 (BRAVE-3), study presented at the

American College of Cardiology 2008 Scientific Sessions/i2 Summit-SCAI Annual Meeting.

### 5.2 Eptifibatide

Eptifibatide is a cyclic heptapeptide. The small molecule is a highly specific, reversible, intravenously administered GPIIb/IIIa receptor antagonist that acts at the final common step of the platelet aggregation pathway. The plasma elimination half-life is approximately 2.5 h [65].

IMPACT II (Integrilin to Minimize Platelet Aggregation and Coronary Thrombosis II) showed clinical benefit of eptifibatide when compared to placebo in lowering clinical endpoints at 30 days in patients undergoing PCI. In this study there was a lack of dose–response relationship between the treatment regimen and the clinical outcome, which was likely due to suboptimal inhibition of platelet aggregation [99]. A new dosing regimen for eptifibatide was established to achieve 90% platelet inhibition in more than 90% of the patients (PRIDE study). The new dosing regimen was tested in the ESPRIT (Enhanced Suppression of the Platelet IIb-IIIa Receptor with Integrilin Therapy) trial, which enrolled patients receiving coronary stents. The trial showed that routine use of eptifibatide was associated with a robust reduction of ischemic endpoints. The magnitude of these risk reduction with eptifibatide was similar to that reported in previous trials with abciximab [100–103].

### 5.3 Tirofiban

Tirofiban is a nonpeptide molecule that blocks the GPIIb/IIIa receptor reversibly. Platelet inhibition greater than 90% is attained by the end of the 30-min infusion and tirofiban has a half-life of approximately 2 h [65].

The results of RESTORE (Randomized Efficacy Study of Tirofiban for Outcomes and Restenosis) with tirofiban broadened the spectrum of GPIIb/IIIa antagonists that can achieve reduction of clinical ischemic events after PCI [104]. Even when there are differences in the reported reduction of relative risk with all three GPIIb/IIIa inhibitors, variation in study design, patient population and definitions of clinical endpoints make it difficult to compare these compounds using the information derived from these trials. TARGET (Do Tirofiban and ReoPro Give Similar Efficacy Trial), the first head-to-head comparison in patients undergoing coronary stenting, showed abciximab was superior to tirofiban in reducing ischemic events with no difference in bleeding. These results may be associated to differences in pharmacokinetics, as well as in the binding site and selectivity of the agent [105–107]. The results of TARGET cannot be extrapolated to eptifibatide, and there is not a specific trial comparing this compound to abciximab.

### 5.4 Oral GPIIb/IIIa Inhibitors

In contrast to the efficacy of intravenous IIb/IIIa inhibitors in ACS and as adjunctive therapy in PCI, the studies with oral IIb/IIIa inhibitors have not shown any benefit, but there are increased bleeding events and mortality with long-term use of these agents [108–110].

The decrease of adverse clinical outcomes with xemilofiban in the ORBIT (oral glycoprotein IIb/IIIa receptor blockade to inhibit thrombosis) study was not seen in the larger EXCITE (Evaluation of Xemilofiban in Controlling Thrombotic Events) trial [111]. Comparable negative results were evident with sibrafiban in the SYMPHONY (Sibrafiban versus Aspirin to Yield Maximum Protection from Ischemic Heart Events Postacute Coronary Syndromes) trial [112] and with orbofiban in the prematurely canceled OPUS-TIMI 16 (Orbofiban in Patients with Unstable Syndromes—Thrombolysis in Myocardial Infarction 16) trial [113, 114]. The 2nd SYMPHONY study and BRAVO (Blockage of the GPIIb/IIIa Receptor to Avoid Vascular Occlusion) studies were terminated early because of negative results [110]. A number of potential mechanisms have been suggested for the failure of oral IIb/IIIa inhibitors. Potential explanations may include the presence of partial agonist activity of these compounds, phospholipase A2 polymorphism and other genetic factors, augmented cardiomyocyte apoptosis via caspase-3 activation, or suboptimal dosing with inadequate effects on platelet aggregation [26]. High levels of inhibition are not tolerable for chronic use because of excess bleeding, whereas low levels of inhibition may not be enough to reduce recurrent thrombotic events and in fact increase the risk of thrombotic events by inducing platelet activation and thrombin generation, and differences in the pharmacokinetic profiles of the different agents may be related to outcomes [110].

## 6 NOVEL ADP RECEPTOR ANTAGONISTS

New ADP receptor antagonists are being developed and are currently in advanced stage testing for use in patients with coronary artery disease (see Table 3). Antiplatelet agents with a faster onset of action could be valuable in the treatment of patients destined for PCI [17]. These newer agents appear to have characteristics that may solve the potential problems derived from limitations associated with clopidogrel

**TABLE 3 New ADP Receptor Antagonists in Clinical Trials**

| Trial | Description | *n* | Main Conclusions | Reference |
|---|---|---|---|---|
| JUMBO TIMI 26 | Prasugrel vs. clopidogrel in patients undergoing elective or urgent PCI—dose-ranging safety trial | 904 | Low rates of bleeding in both groups with no difference between groups<br>Favorable trend in incidence of death, MI, stroke, or target vessel thrombosis at 30 days (study not designed to assess efficacy) | 115 |
| TRITON TIMI38 | Prasugrel (60 mg LD and 10 mg MD) compared with standard dose clopidogrel (300 mg LD and 75 mg MD) in patients with ACS undergoing PCI | 13608 | Greater reduction in ischemic events with prasugrel<br>Greater bleeding risk with prasugrel<br>Populations at greater risk of bleeding: history of stroke or TIA, age greater than 75 years, weight less than 60 kg | 116 |
| PRINCIPLE TIMI44 | Prasugrel (60 mg LD and 10 mg MD) compared with high-dose clopidogrel (600 mg LD and 150 mg MD) in patients with elective PCI | 201 | Greater platelet inhibition with prasugrel after LD and MD<br>More rapid onset of antiplatelet effects with prasugrel<br>Less interindividual variance in response and less hyporesponsiveness with prasugrel<br>Bleeding events tended to be higher with prasugrel (not statistically significant)<br>Trial not powered to detect clinical efficacy differences | 117 |
| DISPERSE 2 | AZD6140 (90 or 180 mg) vs. clopidogrel (300 mg LD and 75 mg MD) in patients with NSTEMI | 990 | No difference in major bleeding but an increase in minor bleeding at the higher dose<br>Favorable trend in incidence of MI (study not designed to assess efficacy) | 118 |
| PLATO | AZD6140 vs. clopidogrel in patients with NSTEMI or STEMI | 18000 | Ongoing (no results available) | NA |
| CHAMPION-PCI and -PLATFORM | Cangrelor vs. clopidogrel in patients undergoing PCI | NA | Ongoing (no results available) | NA |

*n*, number of subjects in trial; ASA, aspirin; CV, cardiovascular; CVD, cardiovascular disease; STEMI, ST-elevation myocardial infarction; LD, loading dose; MD, maintenance dose; DM, diabetes mellitus; MI, myocardial infarct; CABG, coronary artery bypass graft; NA, not available.

use, such as the considerable interindividual variability in response, the slow onset of action, and the irreversible nature of the inhibitory effect [24]. The novel compounds include an oral, irreversible thienopyridine agent (prasugrel) and two reversible nonthienopyridine agents (AZD6140 and cangrelor).

### 6.1 Prasugrel

The oral thienopyridine prasugrel (CS-747 or LY640315) is a prodrug, and the active metabolite binds irreversibly to the P2Y12 receptor, resulting in a faster and more potent antiplatelet effect than clopidogrel. Prasugrel must be metabolized by cytochrome-dependent pathways to its active form. However, unlike clopidogrel, prasugrel requires only one cytochrome P450-dependent oxidative step to generate the active metabolite, and this may underlie the faster metabolic conversion and onset of action of prasugrel compared with clopidogrel [17]. Inhibition of ADP-induced platelet aggregation is achieved more rapidly and consistently (with less interindividual variation) than with clopidogrel. Poor responders to clopidogrel are responsive to prasugrel. Several days off therapy are required for full reversal of antiplatelet effects because prasugrel binds irreversibly to the P2Y12 receptor [24].

Phase I and II trials have demonstrated the safety of prasugrel. JUMBO-TIMI 26 (Joint Utilization of Medications to Block Platelets Optimally—Thrombolysis in Myocardial Infarction 26) showed that prasugrel was as safe as clopidogrel in patients undergoing PCI with no differences in the incidence of bleeding [115]. The safe use of prasugrel and a nonsignificant decrease in incidence of ischemic events seen in this safety study has led to other trials designed to assess both efficacy and safety. TRITON-TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel—Thrombolysis in Myocardial

Infarction 38) confirmed that prasugrel therapy in patients with moderate- to high-risk acute coronary syndromes scheduled for PCI was associated with a reduced rate of ischemic events, including stent thrombosis, but with an increased risk of major bleeding, including fatal bleeding without affecting overall mortality when compared to the standard dose of clopidogrel [116]. A new analysis from the TRITON-TIMI 38 trial presented at the American College of Cardiology 2008 Scientific Sessions/i2 Summit, SCAI Annual Meeting, showed a consistent reduction in stent thrombosis with prasugrel when compared to standard dose of clopidogrel regardless of stent type or stent thrombosis definition used. This reduction was seen early and late after stent implantation. Although relative reductions in stent thrombosis were overall consistent, the absolute benefit in specific groups of patients at higher risk for stent thrombosis was notable. These groups included people with diabetes, stents of more than 20 mm in length, bifurcation stents, and those with MI before presentation. It is not known if this benefit of prasugrel persists when compared to a high loading dose of clopidogrel. Overall, the results of this trial seem to validate the concept that greater platelet inhibition improves clinical outcomes, by reducing ischemic events. Post hoc analyses identified three subgroups with less clinical efficacy and greater absolute levels of bleeding than the overall cohort. These include patients with a history of stroke or transient ischemic attack before enrollment, elderly patients (age greater than 75 years), and those with a body weight of less than 60 kg. These risk factors have been previously associated with increased risk of adverse outcomes while using antiplatelet or antithrombotic agents. The TIMI 38 study was not powered to detect a reduction in the rate of death from cardiovascular causes, with no significant benefit for prasugrel over clopidogrel [116].

The PRINCIPLE-TIMI 44 (Prasugrel in Comparison to Clopidogrel for Inhibition of Platelet Activation and Aggregation—Thrombolysis in Myocardial Infarction 44) study showed in patients undergoing planned PCI that prasugrel (60-mg loading dose and 10-mg maintenance dose) achieves greater platelet inhibition than high dose of clopidogrel (600-mg loading dose and 150-mg maintenance dose) with a more rapid onset. There appeared to be greater levels of inhibition and fewer patients with poor response with standard dose of prasugrel compared to a higher than standard dose of clopidogrel. Even if the use of higher doses of clopidogrel is adopted in the future, greater inhibition of platelet function can be achieved with prasugrel. TIMI 44 was not powered to detect clinical efficacy differences between treatment groups, and few major adverse cardiovascular events occurred [117].

### 6.2 AZD6140

The nonthienopyridine AZD6140 is an orally active, reversible inhibitor of the P2Y12 receptor with distinct pharmacodynamic and pharmacokinetic properties than clopidogrel. Unique characteristics of this agent are that the parent molecule is active, and, therefore, liver metabolism is not needed for antiplatelet effect, and that binding to the receptor is reversible. AZD6140 has a faster onset of action and achieves greater and more consistent inhibition of ADP-induced platelet aggregation than standard doses of clopidogrel. Its short half-life requires dosing twice a day, but offset of effect is not expected to be immediate because of the persistence of AZD6140 in plasma [24].

The DISPERSE 2 (Dose Confirmation Study Assessing Anti-Platelet Effects of AZD6140 versus Clopidogrel in NSTEMI 2) safety trial compared different dose regimens of AZD6140 with clopidogrel. AZD6140 proved to have similar bleeding rates than clopidogrel in patients with NSTEMI [118]. A lower rate of bleeding in AZD6140-treated patients undergoing coronary artery bypass graft (CABG) 1–5 days after stopping study drug indicated a faster recovery of platelet function when compared to clopidogrel-treated patients. However, further studies with larger number of patients are needed to confirm such a benefit with this agent. The use of the reversible agent AZD6140, with a half-life of 12 h, would allow greater flexibility for use of P2Y12 blockers, in managing all patients at the time of presentation with ACS, and stopping treatment for those who need CABG and other types of elective surgery. In DISPERSE 2 overall tolerability of AZD6140 was good, with a higher incidence of dyspnea, hypotension, nausea, and a mild increase in uric acid levels among AZD6140 recipients. In this study, there were not enough clinical events to determine the efficacy of AZD6140 compared to clopidogrel [118]. Results of a large phase III trial are required to evaluate the true efficacy of this agent, which is currently being studied in the large outcomes trial PLATO (Platelet Inhibition and Patient Outcomes) in patients with ACS [26].

In a substudy of DISPERSE 2 AZD6140 inhibited platelet aggregation in a dose-dependent fashion and achieved greater and more consistent levels of inhibition than clopidogrel. AZD6140 further suppressed platelet aggregation in patients previously treated with clopidogrel [119].

### 6.3 Cangrelor

The nonthienopyridine cangrelor (AR-C69931MX) is an intravenous reversible P2Y12 antagonist, and its short half-life could offer a potential safety advantage

over clopidogrel [120]. Near total inhibition of ADP-induced platelet aggregation is achieved within minutes of initiation of intravenous infusion, and restoration of normal platelet aggregation is reached within 1 h after discontinuation [24]. Furthermore, greater P2Y12 receptor blockade can be achieved when compared to clopidogrel [121]. In a phase II study in patients undergoing PCI, there was an acceptable risk of bleeding and adverse cardiac events while achieving rapid, reversible inhibition of platelet aggregation with less prolongation of bleeding time than the GPIIb/IIIa inhibitor abciximab [122]. Patients treated with cangrelor and abciximab showed no significant differences in the incidence of combined major and minor bleeding after 7 days or in the composite incidence of adverse cardiac events after 30 days [17].

In a study in patients with unstable angina or non-Q-wave MI, cangrelor was well tolerated, with no difference in the incidence of serious adverse events compared with placebo [123]. Results from a small study to assess the safety and coronary artery patency of cangrelor as an adjunct to tissue plasminogen activator suggested the potential of this compound as an adjunct to fibrinolysis during treatment of acute MI [124]. The phase III trials CHAMPION-PCI and CHAMPION-PLATFORM (Cangrelor versus Standard Therapy to Achieve Optimal Management of Platelet Inhibition) will assess cangrelor's efficacy when compared to clopidogrel in patients undergoing PCI and will determine the effects of adding cangrelor to usual care in patients requiring PCI [17, 26].

## 7 OTHER ANTIPLATELET AGENTS

### 7.1 Dipyridamole

Dipyridamole was introduced clinically in the 1960s as a coronary vasodilator. Its antiplatelet effect is mediated through different biochemical mechanisms, such as selective inhibition of cyclic guanosine monophosphate (cGMP) phosphodiesterase type V enzyme with enhanced nitric oxide/cGMP signaling, inhibition of adenosine deaminase, reduction in adenosine uptake, and increase of prostanoid release from the endothelium [4, 26]. Dipyridamole is a less commonly used antiplatelet agent that has several effects, including decreased platelet activation, antiatherogenesis through antioxidant properties, and inhibition of restenosis by suppression of smooth muscle proliferation [6].

Addition of dipyridamole to aspirin in the ESPS 2 (European Stroke Prevention Study 2) and the ESPRIT (European/Australian Stroke Prevention in Reversible Ischemia Trial) reduced the relative risk of stroke by about 20% compared with aspirin alone, without causing excess bleeding. The mechanism by which it could reduce the risk for secondary strokes without excess bleeding may be associated to some of its effects beyond platelet inhibition on the vascular wall [125]. After the drug was reformulated to improve its bioavailability, positive results with the new preparation have been reported in ESPS, where dipyridamole appeared to have beneficial effects on stroke prevention without increasing bleeding complications in patients with cerebrovascular disease [4].

Even when this agent has been mainly studied in cerebrovascular disease, there are trials that evaluate its use for secondary prevention of MI. The PARIS (Persantine-Aspirin Reinfarction Study) trial showed no further benefit in death or MI prevention when added to aspirin [126], but dual therapy with dipyridamole and aspirin in PARIS II revealed reduction in the composite endpoint of MI or death after 12 months when compared to placebo [127].

### 7.2 Cilostazol

Cilostazol reversibly inhibits cyclic nucleotide phosphodiesterase type 3 enzyme and adenosine uptake in platelets [128], promotes arterial vasodilation, and suppresses vascular smooth muscle proliferation and hyperplasia of the intima [26]. In CREST (Cilostazol for Restenosis Trial) addition of cilostazol to aspirin and clopidogrel in patients undergoing PCI reduced the rate of restenosis [129]. Cilostazol therapy was effective for prevention of stent thrombosis, restenosis rate, and target lesion revascularization [130]. A small study showed that combination therapy with aspirin and cilostazol for the prevention of stent restenosis was comparable or superior to that of aspirin and clopidogrel in diabetic patients who underwent drug-eluting stent implantation [131]. Cilostazol in addition to an aspirin plus clopidogrel lead to additional inhibition of ADP-induced platelet activation in the primary PCI setting. This suggested that cilostazol may improve low responsiveness to clopidogrel in patients with acute MI who are undergoing stenting [132].

### 7.3 Protease-Activated Receptor Antagonists

Thrombin is a multifunctional serine protease produced at the site of vascular injury that transforms fibrinogen into fibrin, activates platelets, and affects multiple cell types such as endothelial cells, vascular smooth muscle cells, immune cells, and fibroblasts [133]. Platelet activation by thrombin occurs by binding to and cleavage of the extracellular domains of protease-activated receptors 1 and 4 (PAR1 and PAR4) [26, 134]. PAR1 seems to mediate platelet activation at low thrombin concen-

trations, whereas PAR4 is only able to mediate platelet activation at high thrombin concentrations. Thrombin induces platelet activation with shape change, mobilizes P-selectin and CD40 ligand to the platelet membrane, and favors the release of platelet agonists (e.g., ADP, serotonin, TxA2), chemokines, and growth factors. Thrombin inhibition is an emerging target for antiplatelet therapy. Thrombin antagonists, both parenteral (e.g., desirudin, lepidurin, bivalirudin, and argatroban) and oral (e.g., ximelagatran, dabigatran, and odiparcil) have shown efficacy in clinical trials for specific indications [133].

Several peptide and nonpeptide PAR antagonists have been developed. PAR1 antagonists seem to have an advantage over direct thrombin inhibitors since the PAR1 block does not inhibit enzymatic action of thrombin in the coagulation cascade with the consequent minimal bleeding side effects [135].

Thrombin is activated when thrombosis, hemorrhage, inflammation, or tissue damage occurs, and changes in the expression pattern of PARs with an upregulation of PAR1 have been associated with atherosclerosis and hypertension. Direct inhibition of PARs to modulate the effects of thrombin has been assessed. Anti-PAR1 antibodies directed against the thrombin cleavage site have been effective in vitro and in vivo to a lower extent. Peptide-competitive PAR antagonists are currently under development. The PAR1 antagonist RWJ-58259 prevents thrombus formation in nonhuman primates and PAR1 and PAR4 blocking with pepducins (i.e., cell-penetrating lipopeptides) inhibits platelet aggregation [133].

A safety study TRANSCENDENCE (Thrombin Receptor Antagonist for Clinical Event Reduction Over Standard Concomitant Therapies) with the oral PAR1 antagonist SCH 530348 (Schering-Plough) in subjects undergoing nonemergent PCI has been completed and ongoing studies with this compound are TRA 2°P—TIMI 50 (Trial to Assess the Effects of SCH 530348 in Preventing Heart Attack and Stroke in Patients with Atherosclerosis) and TRACER (Trial to Assess the Effects of SCH 530348 in Preventing Heart Attack and Stroke in Patients with Acute Coronary Syndrome) [26]. A phase II study that evaluated SCH 530348 for reducing PCI complications when added to standard antiplatelet therapy with aspirin and clopidogrel showed no increase in major and minor bleeding with a nonstatistically significant reduction in cardiovascular events at the highest dose tested. However, this study was not powered to establish efficacy. A 40-mg loading dose achieved greater than 80% inhibition of platelet aggregation in 2 h in up to 96% of the subjects, while maintenance doses (1 and 2.5 mg) sustained this level of inhibition at 30 and 60 days in all subjects [133]. In addition, there are a number of ongoing studies to evaluate the safety and tolerability of another PAR1 antagonist, E5555 (Eisai Medical Research Inc.) and its effects on markers of intravascular inflammation in subjects with CAD and ACS [26].

Simultaneous block of PAR1 and PAR4 seems to cause more effective inhibition of thrombin-induced platelet activation than antagonism of either receptor alone [136]; however, further investigation is needed to evaluate the effect of this synergic block on clinical outcomes.

## 8 EFFICACY VS. SAFETY

Optimal platelet inhibition requires a balance between minimizing the degree of ischemic risk and the possibility of bleeding.

### 8.1 Variable Response to Antiplatelet Therapy

Biologic processes are variable, and, accordingly, there is a variability of response to medications. The effect of any antiplatelet agent can be quantitated as the change in platelet activation and aggregation induced by the pharmacological intervention. This response to the therapeutic agent may fluctuate in different individuals. Response variability and nonresponsiveness have been demonstrated with both aspirin and clopidogrel. However, a specific and reliable laboratory method to identify nonresponse has not been accepted uniformly by different groups. It is not known if a laboratory test that detects nonresponse predicts future clinical events, and whether changing therapy based on the test result is beneficial to the patient. Until these links are evaluated within large trials, nonresponse in the laboratory cannot necessarily be ascribed as a cause of thrombosis. Therefore, it is still not yet clinically useful to test for nonresponse and change a patient's therapy on the basis of a laboratory test except in research trials [8].

### 8.2 Stent Thrombosis

Drug-eluting stents (DES) have been shown to reduce restenosis more effectively compared with bare metal stents (BMS) with similar risk of mortality [137–139]; however, DES may be associated with late stent thrombosis at discontinuation of clopidogrel and/or aspirin [140]. Premature discontinuation of clopidogrel therapy has been correlated with stent thrombosis leading to an increased risk for death. However, the wide window of thrombotic risk, which is the median time to late stent thrombosis after withdrawal of clopidogrel, and the fact that most cases of late stent thrombosis are not related to nonadherence to clopidogrel dispute the critical role

of compliance and suggests there may be additional mechanisms involved in this setting [38]. A prospective observational cohort study showed that nonresponsiveness to clopidogrel seems to be a strong independent predictor of stent thrombosis after 6 months of follow-up in patients receiving sirolimus or paclitaxel eluting stents. Posttreatment platelet aggregation after a 600-mg loading dose of clopidogrel may be a marker of the risk of stent thrombosis since patients with platelet aggregation greater than 70% after treatment had nearly fourfold increase in definite or probable stent thrombosis as compared with clopidogrel responders [141]. As DES thrombosis is associated with MI and mortality rates, there is a need for further studies to identify predictors of stent thrombosis and clarify the appropriate duration of antiplatelet therapy [142].

### 8.3 Bleeding

The major side effect of antiplatelet therapy is hemorrhage, and the risk of bleeding must be balanced against the risk of an atherothrombotic event. For example, a meta-analysis in patients with vascular disease showed that daily low-dose aspirin (75–150 mg) reduced the risk of major cardiovascular events (nonfatal MI, nonfatal ischemic stroke, or vascular death) by 32% and the risk of major bleeding was increased by around 50%; since these patients are at high risk of atherothrombotic events, a significant benefit of aspirin therapy persisted [6]. Overall, the risk–benefit ratio favors the use of dual antiplatelet therapy in acute coronary syndromes or after PCI, whereas it does not support its use for primary prevention [26].

### 8.4 Adverse Drug Reactions

Aspirin use is associated with symptomatic gastrointestinal disturbances in 2–10% of individuals, and hypersensitivity in 0.3% of those who use it. Clopidogrel tolerability is similar to aspirin. Ticlopidine is linked to severe neutropenia in 0.8–1% of individuals. In the CAPRIE study, clopidogrel is associated with less gastrointestinal bleeding than aspirin, but there is a higher bleeding risk in the elderly population. Clopidogrel has a lower risk of neutropenia than ticlopidine and thrombocytopenic purpura is reported rarely [2]. The major complication with GPIIb/IIIa inhibitors is bleeding and its use may be associated with thrombocytopenia [143].

### 8.5 Combined Use of Anticoagulants and Antiplatelet Drugs

The combination of anticoagulants and antiplatelet agents is indicated in the treatment of acute arterial thrombosis, and when a patient has multiple disorders the use of both anticoagulant and antiplatelet therapy may be justified or required (e.g., coexistence of atrial fibrillation and intracoronary stent, concomitant prothrombotic venous and arterial disease, valvular heart disease coupled with coronary artery disease, heart failure, and acute coronary syndrome) [144].

For the initial and long-term management of acute coronary syndromes combination therapy with anticoagulant and antiplatelet agents is more effective than antiplatelet therapy alone but increases the risk of bleeding. No benefits have been shown for continuing low-molecular-weight heparin beyond the first week in aspirin-treated patients with NSTEMI [145]. Because of the risk of bleeding, determination of the intensity and duration of combined treatment requires careful assessment of the specific patient.

A large number of new oral direct thrombin inhibitors and oral factor Xa inhibitors are being directly compared with existing anticoagulants for the prevention and treatment of arterial thrombosis [145].

## 9 SPECIAL CONDITIONS

### 9.1 Peripheral Artery Disease

Peripheral arterial disease (PAD) is associated with atherosclerosis in the coronary and carotid arteries, leading to increased incidence of MI, ischemic stroke, and cardiovascular death [146]. Patients with PAD manifest increased platelet aggregation, higher levels of soluble platelet activation markers, greater thrombin generation, and altered fibrinolytic potential. These changes are consistent across the different stages of PAD and justify considering antithrombotic prophylaxis in all such patients [147].

PAD is characterized by a very high rate of mortality due mainly to stroke and MI. Antiplatelet therapy decreases mortality and cardiovascular events, particularly MI and ischemic stroke, among high-risk patients with PAD. Chronic antiplatelet treatment improves patency rates among patients with peripheral arterial bypass grafting or angioplasty and is the standard of care for subjects undergoing arterial revascularization [148, 149]. Antiplatelet treatment is indicated in virtually all patients with PAD. Aspirin, 75–325 mg per day, is considered as first-line treatment, and clopidogrel, 75 mg per day, is an effective alternative [146]. The U.S. Physicians' Health Study shows that chronic administration of low-dose aspirin to apparently healthy men reduces the need for peripheral arterial surgery [150]. Low-dose aspirin has been reported to reduce the incidence of vascular events in PAD patients, including

those with concomitant type 2 diabetes [151]. However, the study was underpowered to reach definitive conclusions on the clinical efficacy of aspirin in the PAD population [152]. Aspirin does not improve claudication, but it delays the progression rate, and reduces the need for intervention and graft failure in patients with revascularization procedures [148]. The Antithrombotic Trialists' Collaboration report analyzed 42 randomized trials that evaluate antiplatelet therapy in over 9200 patients with PAD and supports the use of these agents [147]. CAPRIE included more than 6400 patients with symptomatic PAD, and after 2 years of follow-up clopidogrel further reduced the relative risk of MI, ischemic stroke, or vascular death when compared to aspirin, especially in subjects with PAD [35–37]. Even though the CHARISMA trial showed no overall advantage of clopidogrel addition to low-dose aspirin, there was a significant benefit from dual antiplatelet therapy with clopidogrel plus aspirin in patients with symptomatic PAD [48]. Such patients may benefit from antithrombotic therapy beyond aspirin alone, but this needs to be validated in future trials. Currently, antiplatelet therapy with aspirin or clopidogrel is recommended in all patients with PAD, including asymptomatic individuals with an abnormal ankle-brachial index (ABI). The optimal aspirin dose for the prevention of cardiovascular and limb-related events has not been established and a daily dose between 75 and 325 mg should be used. Even when efficacy data favor clopidogrel for patients with PAD, other factors such as comorbid conditions, tolerability, and cost must be considered when choosing the antiplatelet agent, and routine use of dual antiplatelet therapy with clopidogrel and aspirin is not recommended unless needed for another indication [149].

In the CASTLE (Cilostazol: A Study in Long-term Effects Long-Term Safety of Cilostazol in Patients with Peripheral Artery Disease) study all-cause or cardiovascular mortality was similar for cilostazol when compared to placebo, and serious bleeding events appeared not to be increased by cilostazol. However, the study was underpowered to detect a small adverse impact of cilostazol on mortality, and adherence to study medication was poor with over 60% of participants discontinuing therapy by 36 months [153]. Several studies have compared cilostazol with placebo in patients with intermittent claudication (IC), with improvement in maximal walking distance, and pain-free walking distance with cilostazol [154, 155]. Cilostazol has vasodilatory effects, antiplatelet properties, and vascular antiproliferative effects. The mechanism by which it increases walking distance in patients with IC has not been completely defined, but it appears to relate to its cyclic adenosine monophosphate (cAMP)-mediated vascular properties [156].

### 9.2 Ischemic Stroke and Transient Ischemic Attack

Antiplatelet therapy is indicated for the treatment of ischemic stroke or transient ischemic attack (TIA). It has been seen that aspirin reduces subsequent occlusive vascular events, including recurrent stroke, by about 25% [157]. Low-dose aspirin alone or sustained-release dipyridamole alone were equally effective in stroke and TIA prevention, and combination therapy showed additive effects being more effective than the single agents [158]. The Second European Stroke Prevention Study (ESPS2) reported that antiplatelet therapy did not influence the severity of recurrent stroke but seemed to lengthen the time the patient remained free from a recurrent stroke [159, 160]. However, combination therapy with aspirin and clopidogrel provided little benefit compared with either drug alone but increased the risk of serious bleeding [157]. MATCH showed that adding aspirin to clopidogrel in high-risk patients with recent ischemic stroke or TIA did not reduce major vascular events but increased the risk of life-threatening or major bleeding [161]. Clopidogrel is an effective alternative for long-term treatment of survivors of ischemic stroke or TIA that are intolerant to aspirin [157].

Recent evidence suggests that the risk of stroke in the first few months after TIA is higher than previously realized. In general, aspirin (50–325 mg/day) is the first line of treatment to prevent future stroke. Other antiplatelet agents such as clopidogrel and dipyridamole may be given. There is no evidence to prove that using a 300-mg loading dose of clopidogrel is superior (or inferior) to aspirin in the acute setting. However, among patients with TIA secondary to an acutely symptomatic carotid stenosis, the CARESS (The Canadian Registry of Palvizumab) study suggested that dual antiplatelet therapy with clopidogrel and aspirin was more effective than aspirin alone in reducing the risk of asymptomatic embolization and stroke [162].

### 9.3 Diabetes Mellitus

Atherosclerotic disease, including ischemic heart disease, stroke, and peripheral disease, accounts for the majority of morbidity and mortality associated with diabetes mellitus (DM). Several mechanisms may explain the increased atherothrombotic risk in diabetic patients, including other cardiovascular risk factors frequently present in this population (e.g., hypertension, dyslipidemia, and obesity), and other factors specific to the diabetic population (e.g., hyperglycemia, insulin resistance, and pro-inflammatory and prothrombotic status). The prothrombotic status is related to endothelial dysfunction, impaired fibrinolysis, increased coagulation factors,

increased platelet reactivity, and reduced responsiveness to oral antiplatelet agents [163].

Platelet dysfunction has been reported in patients with type 2 DM treated with standard dose of clopidogrel and aspirin, when compared to nondiabetic patients. Increased platelet aggregation and activation was observed acutely after a 300-mg loading dose of clopidogrel and persisted after long-term therapy [164, 165], with a high proportion of clopidogrel nonresponders in the diabetic population [165]. Diabetic individuals with ACS had a lower response to a 600-mg clopidogrel loading dose as measured by platelet aggregation, and suggested that diabetes has a substantial influence on residual platelet activity [166].

OPTIMUS (Optimizing Anti-Platelet Therapy In Diabetes Mellitus) evaluated the impact of a high clopidogrel maintenance dose in diabetic patients with previously established suboptimal clopidogrel response to standard doses. The study showed that a high 150-mg maintenance dose of clopidogrel was associated with enhanced antiplatelet effects compared with a standard 75-mg dose in high risk diabetic patients. However, despite the overall improvement in platelet function profiles in patients treated with the high maintenance dose, response to antiplatelet therapy remained variable, and a significant proportion of patients showed persistent platelet hyperreactivity. The clinical implications of this are not known [167]. High platelet reactivity determined in diabetic patients with coronary artery disease while on chronic dual antiplatelet therapy has been associated with a higher risk of long-term adverse cardiovascular events [168]. These findings draw attention to the potential need for more effective antithrombotic strategies and individualized therapy may be required, especially in high-risk populations, such as diabetic patients.

Availability of new and more potent P2Y12 receptor antagonists, currently under development, and tailored antithrombotic approaches with currently approved medications will represent an important approach to treat diabetic patients and help reduce their thrombotic risk [163]. In TIMI 38 prasugrel showed superior efficacy in specific subgroups. In regard to the primary endpoint, the benefit of prasugrel tended to be greater among patients with diabetes than among those without diabetes [116].

## 10 MONITORING PLATELET FUNCTION AND ANTITHROMBOTIC THERAPY

Even when monitoring anticoagulation is standard practice, monitoring antiplatelet therapy has not been fully adopted as a way to assess antithrombotic response. Variability in platelet inhibition by standard doses of aspirin and/or clopidogrel in patients with coronary artery disease may suggest that using fixed doses of these agents for all patients may lead to suboptimal clinical outcomes [169]. For patients with coronary artery disease, the potential utility of platelet function tests and point-of-care (POC) instruments is to monitor the efficacy of antiplatelet therapy and predict clinical outcomes [56]. No single test can capture all aspects of platelet function and no conclusive link has been shown between clinical outcomes and results from platelet function tests [170].

Light transmission aggregometry (LTA) is still considered as the gold standard of platelet function testing. This method has been the most widely used technique for monitoring the effects of antiplatelet agents (e.g., aspirin, clopidogrel, other P2Y12 inhibitors, and GPIIb/IIIa inhibitors) and to predict clinical outcomes. In this procedure, separated platelet-rich plasma is stirred under low-shear conditions, and platelets form aggregates after addition of various agonists. Conventional LTA requires large sample volumes, immediate processing and lengthy processing time, specialized equipment, and expertise to perform the tests [8, 56].

The VerifyNow instrument (Accumetrics) is a fully automated POC test. Blood sample tubes are simply mixed prior to insertion onto a specialized cartridge placed in the instrument. Aggregation is monitored by light transmission through two duplicate reaction chambers in each cartridge. There are specialized cartridges available for measuring platelet response to either aspirin or clopidogrel and other P2Y12 antagonists. The VerifyNow Aspirin cartridge contains fibrinogen-coated beads and a platelet activator (metallic cations and arachidonic acid) to stimulate the COX-1 pathway, and the test should give similar results to those obtained by arachidonic-acid-induced LTA. The VerifyNow P2Y12 cartridge uses prostaglandin (PG) E1 in addition to ADP to increase intracellular cAMP, enhancing the sensitivity and specificity of the test for ADP-induced activation of platelets via P2Y12 [8]. This method has been used to predict outcomes in patients undergoing PCI, and it is easy and fast to use and correlates with turbidimetric aggregometry [56].

Thromboelastography (TEG) has been traditionally used to determine the risk of bleeding and as a guide to transfusion requirements [8]. TEG analyzes the viscoelastic changes that occur during coagulation, providing a graphical representation of the fibrin polymerization process, which allows a complete evaluation of the process of clot initiation, formation, and stability, using whole blood or plasma. This technology has been applied to the monitoring of antiplatelet drugs [171]. The platelet mapping technique quantifies the contribution of arachidonic-acid-induced platelet aggregation and/or

ADP-induced aggregation to the overall tensile strength of a platelet-fibrin clot and correlates with turbidimetric aggregometry [56].

The expression of activation-dependent receptors on platelets (e.g., P-selectin and GPIIb/IIIa) at baseline and after stimulation can be quantified by flow cytometry with monoclonal antibodies. This technique has been useful to evaluate pharmacologic effects, but less information is available correlating receptor expression and clinical outcomes. Platelet–leukocyte aggregates have been measured as a marker of platelet activation and may be a more stable measure of acute coronary syndromes compared with P-selectin [56]. The phosphorylation of VASP, an intraplatelet actin regulatory protein, is dependent on the level of activation of the P2Y12 receptor, which is targeted by clopidogrel and other agents in this class. In the flow cytometric-based VASP assay ADP and prostaglandin E1 (PGE1) are used and the degree of VASP phosphorylation is measured, which is proportional to the level of inhibition of the P2Y12 receptor [8]. The platelet reactivity index (PRI) is the difference in VASP fluorescence intensity between resting (+PGE1) and activated (+ADP) platelets [172]. Advantages of this test to measure the effect of antiplatelet drugs include specificity for the P2Y12 signaling pathway and the stability of the method compared with aggregometry [56].

There is significant variation in the response of individuals (patients and normal controls) to aspirin, clopidogrel, and GPIIb/IIIa antagonists as measured by various platelet function tests [8]. Platelet activation and the occurrence of thrombotic events are mediated by multiple signaling pathways, and a compound directed against a single pathway cannot be expected to prevent the occurrence of all events. Treatment failure or nonresponsiveness to an antiplatelet agent may indicate persistent activity of the specific target of the antiplatelet agent and is not sufficient evidence of drug "resistance." Since no single test encompasses the complexity of platelet biology and function, it may be problematic to correlate platelet function or drug-related inhibition with clinical outcomes [56].

The optimal level of platelet inhibition has not been established, but it is thought that higher levels of inhibition and greater consistency of response will improve outcomes as long as bleeding events can be controlled or prevented [2, 3]. For example, in TRITON-TIMI 38 prasugrel achieved greater inhibition of platelet aggregation than clopidogrel, which was associated to better clinical outcomes [116].

The clinical usefulness of platelet function tests for monitoring different patient populations using antiplatelet therapy is not clear. There is lack of studies to address the clinical usefulness of modulating therapy based on laboratory findings [24], and further studies are needed to establish a link between inadequate platelet inhibition and cardiovascular thrombotic risk. Before antiplatelet monitoring can be recommended in clinical practice, more trials need to be carried out to answer basic questions on its clinical utility and cost-effectiveness. Until then, monitoring of antiplatelet therapy should be performed for investigational purposes only [22]. Currently, there are no uniformly accepted methods to measure platelet reactivity or to quantify the extent of platelet inhibition after antiplatelet therapy. Therefore, specific treatment guidelines for patients who exhibit high platelet reactivity during clopidogrel or aspirin therapy are not available [2].

## 11 CONCLUSIONS AND FUTURE PERSPECTIVES

Aspirin, ticlopidine, clopidogrel, and IIb/IIIa inhibitors have been widely used in ACS and following bare metal and drug-eluting stent placement. Disadvantages of these agents include a potential increase in bleeding events, individual variability in response, and other clinical side effects. Clopidogrel is superior to aspirin in reducing ischemic vascular events in high-risk patients and has improved gastrointestinal tolerance but is associated with rash, diarrhea, and adverse hematologic outcomes. Combination antiplatelet therapy with aspirin and a thienopyridine is the optimal currently available combination following PCI and in patients with an ACS. There is individual variability in platelet inhibitory response to both aspirin and clopidogrel, but the prevalence depends on the definition used (clinical events vs. pharmacodynamic testing) as well as the specific laboratory assays used. Even when clopidogrel nonresponsiveness can be decreased by higher doses, interindividual variability persists and nonresponse cannot be eliminated. Although there is evidence that monitoring the effects of antiplatelet therapy may help identify patients at an increased risk of developing ischemic events, and multiple studies suggest that platelet reactivity before and after PCI correlates directly with adverse clinical outcomes, current clinical guidelines do not support routine screening for antiplatelet drug response. Large randomized clinical trials will better define the link between the level of platelet inhibition in vitro and the clinical benefit derived from antiplatelet therapy.

Current advances in the development of new antiplatelet agents will provide a wider selection of therapeutic options for the management of cardiovascular patients. Some of these new compounds may be more effective and safer to use in subjects at risk of ischemic cardiovascular events.

# GASTROINTESTINAL DISORDERS: A FOCUS ON ACID-SUPPRESSIVE AGENTS

Brian Hemstreet
*University of Colorado School of Pharmacy, Anschutz Medical Campus, Aurora, Colorado*

## 1 INTRODUCTION

During the late nineteenth century many theories were conceived within the medical community that development of some gastric disorders, particularly gastric ulceration, was somehow related to the secretion of gastric acid [1]. Hypersecretion of gastric acid was thought to be the main underlying defect leading to not only gastric ulceration but also in the development of erosive lesions within the esophagus. Subsequent research into the physiology of gastric acid secretion helped to delineate the main stimuli for acid secretion, and much interest was focused on gastrin as the main target for attenuation of acid secretion, while others touted histamine as the major contributor and next potential drug target [2]. An infectious etiology of peptic ulcer disease was also proposed at this time but received little interest from a research standpoint until later in the twentieth century.

Early attempts at treating acid-related disorders focused on neutralization of gastric acid with alkaline substances, such as milk, sodium bicarbonate, calcium carbonate, or bismuth. Dietary interventions were implemented as additional adjunctive treatments and often included ingestion of bland foods and use of smaller more frequent meals [1–3]. Alternatively, surgical gastrectomy or vagotomies were also less favorable options for patients unresponsive to these interventions. As more research into the physiology of gastric secretion accumulated, the focus of drug development turned more toward inhibition of the production and secretions of gastric acid.

The production and secretion of gastric acid is facilitated by the presence of greater than one billion parietal cells located in the mucosa of the stomach. These parietal cells secrete hydrochloric acid in response to various neuronal and hormonal stimuli [4]. The main external stimulus for gastric acid secretion is oral intake of food. Following stimulation, gastric acid secretion occurs in three phases. The cephalic phase is triggered by sight and smell of food, while the gastric and intestinal phases are regulated mainly by distention of the stomach, and breakdown products of protein and other ingested nutrients. At the level of the parietal cell, the three primary molecular mediators of acid secretion are acetylcholine, histamine, and gastrin [5, 6]. Gastrin, stored in antral G cells, is released into the bloodstream in response to food intake or increases in gastric pH [4]. As mentioned previously, cholinergic input resulting from innervation of the stomach by the vagus nerve leads to local release of acetylcholine and stimulation of muscarinic $M_3$ receptors on the basolateral membrane of the parietal cell. Stimulation of the cholycystokinin$_B$ ($CCK_B$) receptor by gastrin, or the $M_3$ receptors by acetylcholine receptor on the parietal cell, ultimately results in increased cytosolic concentrations of calcium. This in turn leads to stimulation of histamine release from enterochromaffin-like (ECL) cells. Histamine stimulates the $H_2$ receptor on the parietal cell, leading to increases in cytosolic cyclic

adenosine monophosphate (cAMP). Ultimately, this initiates the production of gastric acid.

The final step in acid production following stimulation of the parietal cell is the secretion of $H^+$ from the secretory cannaliculus, located on the apical membrane of the parietal cell. This secretion is accomplished by migration of an enzyme, $H^+$, $K^+$-adenosine triphosphatase ($H^+$, $K^+$-ATPase), from the cytosol to the membrane of the cannaliculus into which it becomes integrated [3–5]. The $H^+$, $K^+$-ATPase, also known as the proton pump, releases a hydrogen ion into the gastric lumen in exchange for a potassium ion. The concentration of $H^+$ in the gastric lumen results in lowering of gastric pH to less than 1. In contrast, both prostaglandins and somatostatin serve as inhibitory mediators of gastric acid secretion and thus serve as necessary counterregulatory measures [4].

## 2 NEED FOR ACID-SUPPRESSIVE AGENTS: AN OVERVIEW OF ACID-RELATED DISEASES

The need for drug therapy that targets gastric acid secretion stems from the wide variety of clinical conditions in which gastric acid plays a significant role. In North America alone, upper gastrointestinal complaints related to diseases potentially responsive to acid suppression such as gastroesophageal reflux disease (GERD), peptic ulcer disease, and dyspepsia are very prevalent and rank among the most common reasons for visits to outpatient clinics and to gastroenterologist offices [7, 8]. Likewise, these diseases significantly impact the health care system due extensive direct and indirect costs incurred with their treatment and consequences, as well as the potential for substantial reductions in quality of life [9]. Several studies have demonstrated that acid-suppressive agents are commonly used by a substantial portion of the patient population for various gastrointestinal conditions [10–12].

Dyspepsia, defined as chronic recurrent pain or discomfort in the upper abdomen, has been estimated to affect up to 25% of the U.S. population [13, 14]. While prevalent, further investigation of dyspepsia may lead to identification of gastric or esophageal abnormalities, peptic ulcer disease, or entities that are distinguished by the absence of esophageal injury and variable responsiveness to acid suppression, such as nonerosive reflux disease (NERD) or functional dyspepsia [15]. In contrast, several factors such as increases in obesity and sedentary behavior have largely led to GERD, becoming one of the most prevalent gastrointestinal disorders in the United States [2, 7, 8]. GERD is defined as the symptoms or mucosal damage resulting from the abnormal reflux of contents from the stomach into the esophagus [16]. Typical symptoms may include heartburn or regurgitation, often in relation to meals, and have been reported in up to 19% of patients reporting upper gastrointestinal symptoms [8]. A severe consequence of GERD includes erosive esophagitis, which may be evident in anywhere from 10 to 60% of patients undergoing upper endoscopy for GERD symptoms [15, 17]. Erosive disease may precipitate severe symptoms and possibly lead to upper gastrointestinal bleeding. Other complications of long-standing untreated GERD include esophageal strictures and the precancerous condition known as Barrett's esophagus.

Acid-suppressive agents also play a significant role in the management and prevention of nonvariceal upper gastrointestinal ulceration and bleeding, the majority of which is caused by peptic ulcer disease (PUD) [18, 19]. Peptic ulcer disease encompasses both duodenal and gastric ulcers, and major causes include both nonsteroidal anti-inflammatory drug (NSAID) use and *Helicobacter pylori* (*H. pylori*) infection. Potent suppression of gastric acid, particularly with proton pump inhibitors (PPIs), can both facilitate healing of established ulcers, as well as prevent ulceration in NSAID users who have established risk factors for this complication of NSAID use [20]. Likewise, acid suppression is a key component in drug regimens used to eradicate *H. pylori* infection, thus facilitating healing of established PUD, and in patients with excessive acid secretion due to hypersecretion of gastrin, as seen in Zollinger–Ellison syndrome [21, 22]. Lastly, critically ill patients often exhibit an elevated risk for stress-related mucosal disease (SRMD) often due to the need for mechanical ventilation or presence of coagulopathies. Acid suppression is the mainstay of prevention of SRMD [23]. Based on the wide variety of disease states and conditions that gastric acid is thought to play a major role, it is clear why the search for both safe and effective acid suppressant agents has been the focus of much research over the last half century.

## 3 FROM BENCH TO BEDSIDE: THE RISE OF HISTAMINE-2 RECEPTOR ANTAGONISTS (H2RAS)

During the continued research into the physiology of gastric acid production, it soon became evident that of the three major chemical inputs for stimulating production of gastric acid, antagonizing histamine at the level of the parietal cell represented the most promising for pursuit of a viable drug option. Anticholinergic medications were initially tried but were found to be neither very effective nor well tolerated, and attempts to isolate a molecule that would effectively inhibit the function of gastrin were met with little success [1, 2, 24]. Histamine, a biologic amine that is synthesized from the amino

acid histidine, is a neurotransmitter that is classified as autocoid. It is found in mast cells, ECLs, basophils, and also in the human central nervous system and bone marrow [25–27]. Histamine's pharmacologic actions vary depending on the area it is released. In addition to its gastric effects, it has appreciable effects on the cardiovascular system, smooth muscle, nervous system, and hemapoetic system [26, 27].

As now known, histamine's effects on gastric acid secretion are mediated by its actions on the histamine receptor, located on the basolateral membrane of the parietal cell. In 1966, a report detailing the presence of different subtypes of histamine receptors has ultimately led to the discovery of four histamine receptor subtypes [1, 28, 29]. The histamine-2 (H2) receptor was subsequently found to function as a stimulus for acid secretion through its associated guanosine triphosphate (GTP)-binding protein, resulting in activation of intracellular adenylate-cyclase [30, 31]. Several attempts to synthesize agents that were based on the structure of histamine and that would ultimately antagonize the H2 receptor were unsuccessful. Through rigorous modeling of gastric acid secretion and study of the H2 receptor, Black and colleagues utilized histamine as a chemical starting point and synthesized an imidazole compound called burimamide that functioned as a viable H2 receptor antagonist and would subsequently be testable in human subjects [26, 27, 29, 32]. This was a major discovery that significantly impacted the treatment of acid-related diseases and ushered in the era of clinical development of various agents within the class of H2RAs, with cimetidine subsequently being released for use in clinical practice in the late 1970s [3, 33, 34].

As a class the H2RAs function as selective, competitive, and reversible antagonists of histamine at the H2 receptor [26, 30, 35]. Structurally, these compounds are weak bases consisting of an aromatic ring joined to a polar group by a flexible four-atom chain (Fig. 1) [26]. Initially, it was thought that the aromatic ring needed to be an imidazole derivative in order to effectively function as an H2RA. Despite the prototype H2RA cimetidine containing the imidazole ring, the subsequent H2RAs developed contained both furan (ranitidine) and thiazole (famotidine and nizatidine) derived ring structures [27, 36]. The length of the side chain determines the degree of binding to the H2 receptor [26]. There is a 20- to 50-fold difference in potency between the four existing agents used in clinical practice, with cimetidine being the least potent, and famotidine the most potent [27, 35, 36]. Ranitidine and nizatidine both have similar potencies. Potency of these agents also depends on the local concentration of histamine, with decreases in the reduction of acid secretion seen in conditions where local concentrations of histamine are highly elevated, such as in the Zollinger–Ellison syndrome [5].

**Figure 1** Structure of the histamine-2 receptor antagonists.

All H2RAs are rapidly absorbed following oral ingestion, reaching peaking serum concentrations in 1–3 h, with bioavailabilities ranging from 40 to 100% [27, 35]. They are widely distributed throughout the body, with mean volumes of distribution of 1.5 l/kg and also exhibit a low degree of plasma protein binding (15–30%) [31]. Cimetidine, ranitidine, and famotidine are primarily metabolized by the liver and then renally excreted, while nizatidine is eliminated primarily via renal excretion [35]. Renal secretion also occurs as a minor route of elimination for both cimetidine and famotidine. All agents are rapidly eliminated via the kidney, with terminal half-lives of 1–4 h [27]. The pharmacokinetic profile of the H2RAs necessitates dose alteration in patients with renal disease. Likewise, both

cimetidine and ranitidine bind to the hepatic cytochrome P-450 enzyme system (CYP450). Cimetidine is a much more potent inhibitor than ranitidine, and use of these agents may result in significant drug interactions between other pharmacologic agents that share this route of metabolism [35]. Following the release of the oral H2RAs, intravenous (IV) dosage forms of cimetidine, ranitidine, and famotidine were also developed for clinical use. The availability of IV dosage forms expanded the role of H2RAs to use in patients who are unable to swallow or in those who require rapid acid suppression [37, 38].

Clinically, all four H2RAs inhibit both basal and meal-stimulated gastric acid secretion [3]. The effects on acid secretion typically occur within after 1–2 h following oral absorption, and in general there does appear to be a direct correlation between plasma concentration of the drug and degree of acid suppression [27, 39]. Evaluating the acid-suppressive effects of H2RAs using pentagastrin stimulation of gastric acid secretion and normal therapeutic doses, the duration above which the serum concentration of the H2RAs is at least able to inhibit 50% of acid secretion ($IC_{50}$) in vivo is roughly 6 h for cimetidine and 10 h for the other agents [27, 35]. However, given the reversible nature of their mechanism, use of H2RAs is met with the rapid development of tolerance to their antisecretory effects within a few days of treatment [5, 40–42]. This has been identified as a significant limitation to the long-term use of H2RAs for the maintenance treatment of acid-related diseases. Mechanisms by which tolerance to H2RAs is thought to occur include hyperstimulation of ECLs with subsequent histamine release as a direct consequence of the increases in gastrin, which accompanies blockade of the H2 receptor, possible upregulation of H2 receptors over time, or increases in parietal cell mass [3, 5, 40, 43]. Interestingly, *H. pylori* infection appears to possibly attenuate the development of tolerance to the acid-suppressive effects of the H2RAs in some patients, while concomitant use of PPIs has been shown to have variable affects on the development of H2RA tolerance [44–46].

As a drug class the H2RAs are generally well tolerated. Short-term transient adverse effects include both diarrhea and headache, while mental status changes and thrombocytopenia have also been reported, particularly in critically ill patients [26, 43]. Cimetidine does exhibit some antiandrogenic activity, leading to the development of loss of libido, impotence, and gynecomastia in some male patients [26].

Given that H2RAs have been used in clinical practice for more than 25 years, they have established efficacy in a wide variety of acid-related diseases. This includes healing of gastric and duodenal ulcers, treatment of GERD and esophagitis, prevention of SRMD, and treatment of *H. pylori* infection when prescribed with appropriate concomitant antibiotics [33, 47–49]. Release of these agents also lead to the reduction in the number of gastric surgeries performed for acid-related diseases [1]. Based on their rapid onset of action, the H2RAs have been useful as "on-demand" therapies for patient-directed treatment of heartburn and regurgitation [16, 50, 51]. Also, based on their favorable adverse effect profiles, these agents have also been approved for use on a nonprescription basis at doses only previously available with a prescription [52, 53]. Based on the increased prevalence of GERD and dyspepsia in the United States, this has allowed easy access to these agents, especially for effective treatment of symptomatic episodes of heartburn [54]. Another potential role for H2RAs is use in patients who experience nocturnal acid breakthrough (NAB) while receiving PPI therapy. This phenomenon is well described in users of PPIs, and use of H2RAs is based on the fact that they inhibit basal nocturnal acid secretion. Several studies have demonstrated that this may be an effective and lower cost strategy for managing NAB compared using twice daily PPI dosing [55–62].

## 4 UNMET NEEDS IN ACID SUPPRESSION: THE DEVELOPMENT OF PROTON PUMP INHIBITORS

The development and release of the H2RAs represented a major breakthrough in the management of acid-related diseases. However, there were drawbacks to their use in clinical practice. These included the ability to target only one of the three stimuli for acid secretion, the development of tolerance with prolonged use, the need for multiple daily dosing, the potential for drug–drug interactions and adverse effects, and the inability to provide sustained acid suppression leading to the relapse of PUD of erosive disease upon withdrawal of the drug in a significant portion of patients [1, 34]. Thus a search for more potent acid-suppressive agents soon was underway. Initially, attempts to synthesize more potent noncompetitive H2RAs with longer durations and of action were unsuccessful. This was based on the fact that the pronounced hypersecretion of gastrin seen with the use of noncompetitive agents led to the development of carcinoid and squamous tumors in early animal models [34]. Early research into the oxyntic cells of frogs revealed an enzyme on the parietal cell that exchanged the potassium for the hydrogen ion, later to be identified in humans as the $H^+$, $K^+$-ATPase, and subsequently referred to as the proton pump. As this enzyme represented the final common pathway for acid

secretion, this was considered a viable area for further pursuit, and in the mid-1970s prototype drugs, the PPIs, which could inhibit the proton pump, were first developed [1, 63].

The PPIs target the human $H^+$, $K^+$-ATPase, which is located in the parietal cell and is a heterodimer consisting of a 1034-amino-acid α subunit, and a smaller 291-amino-acid β subunit [4, 63]. In the resting state this enzyme resides in the cytoplasmic tubulovesicles, while upon stimulation the tubulovesicular membrane fuses into the apical secretory cannaliculus [4, 31]. The $H^+$, $K^+$-ATPase then exchanges $H^+$ for $K^+$ present in the extracellular cannalicular space, resulting in up to a 4-million-fold increase in $H^+$ concentration in this area. This constitutes the final pathway in acid secretion.

There are currently five PPIs marketed for use in the United States: omeprazole, lansoprazole, esomeprazole, pantoprazole, and rabeprazole. The synthesis of the PPIs is based on a common 2-pyridal-methyl-sulphinyl-benzimidazole structural nucleus (Fig. 2) [4, 31, 63, 64]. All of these agents are weak protonatable weak bases with $pK_a$'s in the range of 4–5 [65]. The PPIs are prodrugs, and at physiologic pH the unprotonated forms they are able to cross cell membranes, and thus when administered orally they are able to diffuse into the parietal cell from the bloodstream [64]. These agents then diffuse into the secretory cannaliculus, and upon protonation to their active sulfonamide forms in this acid environment, are able to bind covalently to cysteine residues on the α subunit of the $H^+$, $K^+$-ATPase [4, 64]. This binding is irreversible, resulting in permanent inactivation of the active $H^+$, $K^+$-ATPase. Likewise, the protonated forms of the PPIs are no longer able to cross cell membranes, leading to their further concentration in the secretory cannaliculus and inactivation of newly presented proton pumps [3, 63, 65].

The PPIs not only inhibit basal acid stimulation but also secretion from any source of stimulation, including food intake. Likewise, they inhibit the secretion of pepsinogen, as well as the activity of pepsin [66]. One substantial advantage of the PPIs compared to the H2RAs is the greater degree of acid suppression achieved. In general, potent acid suppression is defined as the ability of a drug to sustain an intragastric pH of greater than 4 for at least 16 h out of a 24-h day [66, 67]. Maintenance above this pH cutoff is associated with improvement in healing of esophagitis and ulceration, reduction in episodes of heartburn, and prevention of SRMD [43, 66–68]. Likewise, the area under the plasma concentration time curve (AUC) is indicative of the total amount of drug reaching the systemic circulation and also correlates well with the degree of gastric acid suppression [69]. The acid-suppressive effects of PPIs peak within the first 4–6 h and last much longer in duration

| PPIs | $R_1$ | $R_2$ | $R_3$ | $R_4$ |
|---|---|---|---|---|
| Omeprazol [(R)-Isomer] | $–OCH_3$ | $–CH_3$ | $–CH_3$ | $–CH_3$ |
| Lansoprazole | — | — | $–OCH_2CF_3$ | $–CH_3$ |
| Pantoprazole | $–OCF_2H$ | — | $–OCH_3$ | $–OCH_3$ |
| Rabeprazole | — | — | $–O(CH_2)_3–OCH_3$ | $–CH_3$ |
| Esomeprazole [(S)-Isomer] | $–OCH_3$ | $–CH_3$ | $–OCH_3$ | $–CH_3$ |

**Figure 2** Structure of the proton pump inhibitors.

compared to H2RAs [4, 34]. The PPIs are able to sustain intragastric pH above 3 for approximately 17 h per day and above a pH of 5 for roughly 9 h per day [3]. The rapidity in conversion to the sulfonamide species is affected by differences in $pK_a$ and the structural instability of the PPIs and does affect how quickly inactivation of the proton pump occurs. Rabeprazole and esomeprazole appear to be converted most quickly, followed by omeprazole and lansoprazole, and lastly pantoprazole [4, 65]. This appears to impact how rapid the acid-suppressive effects of these agents are achieved on the first day of dosing [70]. However, since PPIs only inhibit active proton pumps, their maximal effects on acid suppression is not achieved for several days [65]. Lastly, another major advantage over H2RAs is that tolerance to the acid-suppressive effects of PPIs does not develop over time. This is again related to their irreversible inhibition of the proton pump, thus making these drugs great choices for maintenance of acid-related disorders [66].

An interesting aspect of development of the PPIs has dealt with their unique pharmaceutical and pharmacokinetic properties. All PPIs are acid-labile drugs and are readily inactivated by gastric acid when given orally. This has necessitated the production of oral formulations that utilize enteric coatings or alkaline vehicles to facilitate administration and protect the parent drug [71]. All agents are well absorbed orally, and the actual plasma half-lives of all PPIs are extremely short, ranging from 0.7 to 1.2 h [72]. However, the irreversible nature of their mechanism leads to the prolonged duration of their pharmacologic effects. The oral bioavailabilities do differ among the available agents. Omeprazole and esomeprazole exhibit reduced bioavailability with initial dosing, with increases seen in bioavailability with repeated dosing. This is thought to be secondary to reductions in acid degradation of the drug as gastric pH increases over time [67]. Pantoprazole and lansoprazole have highest overall oral bioavailability [72, 73].

The PPIs should be taken during a fasting state, and prior to a meal in order to ensure that a maximal amount of proton pumps are active at the time of the peak serum concentration in the bloodstream [66]. All the PPIs are highly protein bound and undergo extensive hepatic metabolism by the CYP450 system, with the exception of rabeprazole, which undergoes nonenzymatic reduction to a thioether compound [72, 73]. The major CYP450 isoenzymes involved in the hepatic metabolism of the PPIs are CYP2C19 and to a lesser extent CYP3A4. Despite this, there are few major hepatic drug–drug interactions that occur due to the coadministration of PPIs with substrates of the cytochrome P-450 system. In fact, polymorphisms of the 2C19 enzymes are probably a more significant factor affecting the acid-suppressive profile of these agents [72, 73].

Once omeprazole was developed and marketed for use in the United States, this was followed by the development of lansoprazole, pantoprazole, and rabeprazole. In the search for more efficacious agents, an interesting approach was taken by revisiting the metabolic pathway of PPIs. By exploiting the differing pharmacologic properties of the structural isomers of PPIs, esomeprazole, the (S)-isomer of omeprazole, was subsequently developed for use in clinical practice. This was based on the fact that the metabolism of omeprazole by the CYP2C19 enzyme is stereoselective, with the metabolic rate of the (S)-isomer of omeprazole being lower and less variable than the (R)-isomer [74, 75]. The CYP2C19 enzyme is responsible for the formation of the hydroxy and 5-*O*-desmethyl metabolites of omeprazole, while the CYP450 enzyme is responsible for the development of the sulfone metabolite [74]. Interestingly, both isomers are protonated and converted to the same sulfenamide species, which inhibit the proton pump equally as effective [69, 75]. The differences in the pharmacologic profiles of omeprazole and esomeprazole do, therefore, lie in the differences in their metabolism. Overall the sum of the intrinsic clearances of all three metabolites of esomeprazole is approximately one-third that of the (R)-isomer, indicating a much slower clearance [74, 75]. This translates into a roughly 180% increase in plasma AUC for a 20 mg oral dose of esomeprazole compared to a 20 mg dose of omeprazole, leading to increases in the acid-suppressive effects of esomeprazole compared to the other PPIs [69, 75, 76].

Much like the H2RAs, once the oral PPIs were established as effective agents, research into the development of alternative dosage forms soon commenced. As mentioned previously, all the PPIs are acid-labile agents, and thus require formulation to protect them from gastric acid. This in essence makes them delayed-release products. Some formulations utilize capsules containing enteric-coated beads or spheres (omeprazole, lansoprazole, esomeprazole), while others utilize enteric-coated tablets (pantoprazole, rabeprazole) [71]. The advantage of some capsule formulations is that they can be opened and the contents sprinkled on various soft foods to ease administration. Likewise some products allow the contents to also be mixed with water or other fluids to facilitate administration through nasogastric tubes. Preparations of both lansoprazole and omeprazole suspension, utilizing sodium bicarbonate as a vehicle, were also formulated extemporaneously at many institutions for administration via nasogastric tubes [77]. Lansoprazole has most recently been formulated into an oral suspension, as well as an orally disintegrating tablet that can be dissolved orally or administered via a

nasogastric tube. The newest formulation of PPI on the market is a nonenteric-coated immediate-release omeprazole powder for oral suspension [78, 79]. This formulation results in rapid oral absorption of omeprazole and may have a role in on-demand therapy in those patients who have difficulty swallowing, patients with NAB, or in patients who have delayed gastric emptying [78]. Lastly, lansoprazole, esomeprazole, and pantoprazole have all been formulated into intravenous preparations, which can be given by intermittent bolus injection or by continuous infusion. This allows administration to hospitalized patients with GERD or gastrointestinal bleeding, those patients who are unable to swallow, or in those requiring pharmacologic prevention of SRMD [38, 71, 77, 80].

The superior acid-suppressive effects of the PPIs have resulted in their preferential use in many acid-related disorders compared to H2RAs. This has also been influenced by their favorable adverse effects profile. The most frequently reported adverse events are usually mild in nature and include diarrhea, nausea, abdominal pain, headache, and skin rashes [4]. The PPIs are associated with rebound hypersecretion of gastric acid upon withdrawal of their use. This is presumably due to increases in ECL mass as a result of their stimulation by the increased concentration of circulating gastrin that accompanies PPI use [5, 40]. This hypersecretion of gastrin seen with PPI has not been associated with significant increases in the incidence of gastric carcinoid or carcinomas [4, 66]. It is not totally clear what the consequences of this rebound increase in gastric acid are; however, some studies have documented increased in dyspeptic symptoms upon stoppage of PPIs [5]. Other potential effects of prolonged potent acid suppression include vitamin $B_{12}$ deficiency secondary to impaired release of dietary vitamin $B_{12}$ [66, 81]. A recent trial has also suggested that PPIs may impair dietary calcium absorption, leading to increases in the risk of hip fractures [82]. Lastly, given that gastric acid is thought to sterilize orally ingested nutrients, thus the potential for intestinal overgrowth of bacterial microorganisms with subsequent increases in rates of infection has been another concern with the use of PPIs. This includes increases in the risk of *Clostridium difficile* associated diarrhea, community-acquired pneumonia, and *Campylobacter jejuni* infection [63, 82–85].

Despite these potential adverse events, the PPIs have proven to be the best available agents for the treatment of most acid-related disorders [86]. In general, the PPIs all perform similarly when dosed appropriately for most conditions [87]. Use of PPIs can significantly reduce symptoms related to GERD and facilitate rapid healing of reflux esophagitis [16, 88–90]. They are also effective in preventing rebleeding in patients with nonvariceal upper gastrointestinal bleeding, as well as facilitating healing of gastric and duodenal ulcers and preventing recurrence of PUD [19, 91, 92]. The PPIs are also recommended as first-line agents for the prevention of NSAID-associated ulceration and treatment of *H. pylori* infection when prescribed with appropriate antibiotics [20, 21, 49]. Likewise, they are also very effective in the prevention of SRMD in critically ill patients and are considered the drugs of choice for the Zollinger–Ellison syndrome [22, 43]. While effective and safe, many studies have documented that the PPIs tend to be overused in clinical practice and are often prescribed for patients who do not meet criteria for their use [10, 93–97].

## 5 NEXT STEPS IN THE USE AND DEVELOPMENT OF ACID-SUPPRESSIVE AGENTS

Clearly, the development of H2RAs and PPIs revolutionized the treatment of acid-related disorders in the twentieth century. However, there are still several aspects of these drugs in the treatment of these disorders that are lacking. First and foremost, despite the potent acid suppression achieved with PPIs, there remains a percentage of the population, particularly those with GERD or erosive esophagitis, whose symptoms or disease are nonresponsive to this class of drugs [98–100]. There may also be substantial interpatient variability in response to PPIs, and the currently available agents do not provide 24-h suppression of gastric acid, with some patients experiencing significant NAB [99, 101]. Additionally, acid suppression with PPIs does not totally abolish the gastrointestinal toxicity secondary to NSAID therapy [102]. The use of a PPI that could be given without regards to meals and that may be used for on-demand therapy would also be favorable but has yet to be developed. This has lead to the search for newer agents to meet these needs.

Given that the PPIs have short half-lives, and thus are rapidly eliminated, research has focused on the development of agents with more favorable pharmacokinetic profiles. One such agent is the imidazopyridine PPI tenatoprazole. This agent not only differs in structure but has a much longer 7-h half-life. This offers the opportunity for a longer duration of action and possibly better control of nocturnal acid secretion [87, 102]. Much like the derivation of esomeprazole from omeprazole, the (S)-isomer of tenatoprazole is also being evaluated in human trials to assess its safety and efficacy [101]. Interestingly, some research into newer H2RAs, such as lafutidine, which exhibit more rapid and steady acid suppression in comparison to PPIs, may have a role

in on-demand treatment of acid-related disorders [103, 104].

Other novel approaches to acid suppression are also being researched. This includes agents such as the potassium competitive acid blockers (P-CABs), which bind to the $K^+$ binding region of the proton pump [102]. These agents act in a competitive and reversible manner and do not covalently bind to the $H^+ K^+$ ATPase as PPIs do. This results in a very rapid onset of action [99]. Preliminary results of trials show similar efficacy to esomeprazole [101]. Another class of agents, the $CCK_2$ receptor antagonists, appear to also suffer from the development of tolerance to their effects but may have a role as and adjunctive therapy [101]. Another potential target for reducing acid secretion is the H3 receptor, which is located in presynaptic brain neurons, as well as in the myenteric plexus in the gastrointestinal tract. Agonists of the H3 receptor have shown some promise as potential acid-suppressive agents in animal studies [99].

## 6 CONCLUSION

Acid-related disorders are prevalent in many countries. Research over the last century into the physiology of gastric acid secretion has yielded valuable insight into pathophysiology of many of these disorders. The discovery that histamine, gastrin, and acetylcholine all effect the production of gastric acid paved the way for the development of the H2RAs and PPIs. These agents have subsequently revolutionized the treatment of many acid-related disorders in clinical practice. The H2RAs provide both safe and effective acid suppression but are limited by the development of tolerance and the inability to provide sustained potent acid suppression over the course of a 24-h period. They remain useful for on-demand treatment of symptomatic diseases, such as GERD or dyspepsia, however, their use has been surpassed by superior acid suppression profile of the PPIs.

The PPIs represent the most potent acid-suppressant agents available today. Their irreversible potent acid-suppressant effects and favorable adverse effect profiles have made them the drugs of choice for most acid-related disorder. Tolerance does not develop to these agents, but they are associated with significant rebound acid secretion upon withdrawal, the clinical consequence of which is unknown. Despite their effectiveness, some patients remain unresponsive to the PPIs, and their short pharmacologic half-lives lead to the development of NAB in some patients. The search for longer acting PPIs is underway, with some agents already in clinical trials. The efficacy of other novel approaches to acid suppression, such as H3 agonists and P-CABS, wait to be seen. Thus targeting acid secretion remains a viable area of research for development of new pharmacologic agents.

# PHARMACOLOGY OF VASOPRESSIN AND THE RENIN–ANGIOTENSIN–ALDOSTERONE SYSTEM

Elizabeth J. Brant, Albert Q. Lam, and Julian L. Seifter
*Renal Division, Brigham and Women's Hospital, Boston, Massachusetts*

Pharmacological agents targeted toward renal pathophysiology have had a profound effect in medicine, serving to advance the understanding of both renal disease and normal physiology, and significantly improve disease outcomes in many circumstances. A review of the mechanisms of action of several of these agents will be reviewed here. In addition, new agents active in major hormonal pathways, including antidiuretic hormone (ADH) and the renin–angiotensin system will be introduced.

## 1 ADH ANTAGONISTS

The antidiuretic hormone (ADH), or vasopressin, is a nonapeptide hormone synthesized in the hypothalamus and secreted by the posterior pituitary [1]. It initiates several physiological mechanisms by acting at any of several receptor types, depending on tissue localization [1–4]. ADH stimulation of V1a receptors results predominantly in cardiovascular changes, including vasoconstriction, platelet aggregation, increased force of cardiac contraction, and increased protein synthesis in the myocardium. V1b receptor stimulation increases adrenocorticotropic hormone (ACTH) secretion by the hypothalamus. The primary function of ADH is maintenance of water balance, which is achieved by stimulation of V2 receptors. The net effect is uptake of free water in the collecting duct of the kidney. ADH receptors are found in numerous other tissues, and the role of ADH continues to be elucidated. However, the important role of ADH in water regulation will be the focus of this discussion.

The system by which ADH facilitates water balance is an elegant one. The distal collecting duct of the kidney is, at baseline, impermeable to water [5]. In the setting of increased plasma osmolality or decreased effective circulating volume, ADH levels rise, with subsequent binding of ADH to V2 receptors on the basolateral membrane of principal cells of the collecting duct [4, 5]. The result of binding is the G-coupled protein-mediated synthesis of cyclic adenosine monophosphate (cAMP), with subsequent activation of protein kinase A. Protein kinase A in turn promotes fusion with the apical membrane of vesicles containing preformed aquaporin-2, rendering the heretofore impermeable collecting duct membrane permeable to water [6]. In addition, the rise in cAMP promotes increased transcription of aquaporin-2 [4]. Simultaneous insertion of aquaporin-3 and aquaporin-4 channels into the basolateral membrane allows for the transcellular movement of water, a process driven by the sodium osmotic gradient. As ADH levels decrease in response to restoration of plasma osmolality and/or volume, the aquaporins are endocytosed, and the collecting duct membrane again becomes impermeable to water.

Disturbance of the ADH-mediated pathway that increases activity of ADH leads to a disruption of water balance, as reflected in the development of hyponatremia, and can be seen in such conditions as the syndrome of inappropriate antidiuretic hormone secretion (SIADH), heart failure, and liver disease. The

sequelae of hyponatremia can include mild neurological deficits, such as impaired balance and attention, or even increased morbidity and mortality in the context of cardiac, hepatic, or neurologic disease. Since correction of hyponatremia can ameliorate or even reverse some of these symptoms, medications that can interrupt this pathway are potentially beneficial not only in treating hyponatremia but also in improving survival.

Historically, demeclocycline, a tetracycline antibiotic derivative, has found utility in some cases of SIADH, as well as in cases of paraneoplastic production of ADH-like peptides [7, 8]. Sodium normalization is due to the development of a reversible nephrogenic diabetes insipidus but does not become apparent until 1–2 weeks after initiation of treatment. Lithium, which can also antagonize ADH activity, is not typically used clinically for this purpose because of an unpredictable response and the risk of adverse outcomes, including tremor, cognitive impairment, cardiotoxicity, thyroid dysfunction, and leukocytosis. Like demeclocycline, it causes a reversible nephrogenic diabetes insipidus. Demeclocycline is more predictable than lithium but still requires regular monitoring of plasma levels in order to maintain a level of 2 μg/mL. The most common and important adverse effects of both these medications are severe hypernatremia and nephrogenic diabetes insipidus, the latter being the effect that permits sodium normalization. In addition, there have been reports of acute kidney injury with both drugs, as well as cases of chronic interstitial nephritis with lithium administration. Because of the difficulties in correcting hyponatremia using these medications, typical management involves fluid restriction, liberal salt intake, and hypertonic saline in severe cases.

Drugs are currently being developed that act selectively as antagonists in the ADH pathway, the rationale being that such drugs offer the prospect of decreasing fluid overload and correcting sodium balance without causing or exacerbating other electrolyte disturbances, such as hypokalemia, or inducing renal dysfunction [9], as is seen with loop diuretics, a mainstay of treatment for heart failure and previously the only therapy available to decrease congestion-inducing fluid overload in patients with heart failure [10, 11].To briefly review, loop diuretics, such as furosemide, block sodium uptake in the thick ascending limb of the loop of Henle. The consequent increased sodium delivery to the distal nephron activates tubuloglomerular feedback and the renin–angiotensin–aldosterone axis, with resultant constriction of the afferent arteriole. Renal blood flow can thus be reduced to the point of compromising renal function, which is in itself a significant independent risk factor for mortality in patients with chronic heart failure. Furthermore, decreased renal function can limit the use of angiotensin-converting enzyme (ACE) inhibitors, known to be effective in increasing survival in patients with heart failure. Finally, loop diuretics can lead to potassium wasting, a risk factor for arrhythmias. The hypothesis was that a compound that could inhibit free water reabsorption at the level of the V2 receptor could effect the desired change of reduction of total body water without affecting sodium or potassium balance and without activating tubuloglomerular feedback.

Research has been conducted for more than 20 years in an attempt to develop effective ADH antagonists but with little success until recently [3]. While some formulations worked well in certain animal models, they did not work as well in others and sometimes not at all in human trials [7, 12]. In addition, the response to individual preparations could change with prolonged administration, notably converting from antagonists to agonists. The vaptans, a new class of agents, are proving to be selective and effective ADH antagonists in human trials, and, to date, two of them have been approved for use in the United States: conivaptan (intravenous) and tolvaptan (oral). Other agents (e.g., lixivaptan, satavaptan) are still undergoing investigation for potentially similar applications.

The vaptans are nonapeptide V2 receptor antagonists, and all are benzazepine derivatives [13]. As the name suggests, benzazepines are related to a common family of compounds that includes benzazepinones and benzodiazepines. Overall, this family of molecules affords a number of pharmacological properties, including antitumor activity, analgesia, and, as will be discussed here, vasopressin V2 receptor antagonism. ADH itself binds the transmembrane V2 receptor at the extracellular surface. Even though there is overlap in native ADH and antagonist binding sites, the ADH antagonists do not function by changing the affinity of ADH for its receptors [14]. Rather, the nonpeptide antagonists binding at a different site deep within the transmembrane portion of the receptor. Specificity of receptor binding by the antagonists is primarily related to differences in the shape of the binding pocket between receptor types. Affinity of the individual antagonists is further manipulated by individual amino acid substitutions [15].

Both oral and intravenous conivaptan (YM-087), a combination V1/V2 receptor antagonist, are able to effect an approximately sevenfold increase in urine flow rate, with concomitant decrease in urine osmolality from 600 mosm/L to less than 100 mosm/L, in healthy, normotensive male subjects [16]. There is an associated significant increase in plasma osmolality, with similar degrees of normalization using either formulation. As would be expected, serum ADH levels also increase significantly with conivaptan administration. Peak effect

occurs approximately 2 h after drug administration, with a return to baseline at 12 h. These findings suggest effective inhibition of renal V2 receptors. V1 receptor antagonism, as suggested by the inhibition of vasopressin-induced skin vasoconstriction, was at the limit of significance with intravenous administration of conivaptan, and was transient and statistically nonsignificant with oral conivaptan.

Intravenous conivaptan (50 mg) achieves a mean maximum serum concentration of 2681 ng/mL. The mean apparent volume of distribution is 34 L, with a mean distribution half-life of 0.15 h. The mean half-life of the terminal disposition phase is 3.1 h [16]. A multicenter, randomized, double-blind, placebo-controlled study of 84 patients with euvolemic or hypervolemic hyponatremia (serum sodium 115 to <130 mEq/L) investigated the efficacy and tolerability of intravenous conivaptan in these two groups of patients [17]. Patients assigned to receive conivaptan were administered a 20-mg loading dose administered over 30 min, followed by either 40 or 80 mg per day via a 96-h infusion. The primary efficacy endpoint of change in serum sodium concentration, as assessed by the baseline-adjusted area under the sodium–time curve (AUC), was significantly greater in both groups of patients receiving conivaptan ($6.3 \pm 0.7$ mEq/L with 40 mg/day and $9.4 \pm 0.8$ mEq/L with 80 mg/day) as compared with patients receiving placebo ($0.8 \pm 0.8$ mEq/L). The difference between the two conivaptan groups was not statistically significant, suggesting that the lower dose of intravenous conivaptan is reasonably effective in increasing serum sodium in most patients. Conivaptan also proved to be significantly superior to placebo in all secondary endpoints, including time from initial dose to achieve a 4-mEq/L increase in serum sodium (median 24 h with either dose of conivaptan; achieved at end of study with placebo in a few patients, therefore not estimable); total time a serum sodium 4 mEq/L above baseline was maintained (53 h with 40 mg and 73 h with 80 mg vs. 14 h with placebo); change in serum sodium from baseline to end of treatment; and number of patients with normalized (135 mEq/L) sodium or minimum 6 mEq/L increase in serum sodium concentration (20 patients receiving 40 mg/day, 23 patients receiving 80 mg/day, and 6 patients receiving placebo). These findings, in conjunction with generally good tolerability, suggest that intravenous conivaptan is an effective means of increasing serum sodium in patients with euvolemic or hypervolemic hyponatremia.

Oral conivaptan (60 mg) reaches a mean maximum serum concentration of 664 ng/mL within approximately 1 h after administration [16]. The mean distribution half-life is 1.8 h, with a mean terminal disposition phase half-life of 5.6 h. Bioavailability of oral conivaptan is approximately 44%. A separate 5-day randomized, double-blind, placebo-controlled study was also conducted to assess the efficacy and safety of 40 or 80 mg of oral conivaptan administered in two divided doses versus placebo in patients with euvolemic or hypervolemic hyponatremia [18]. Patients in this study also had a baseline serum sodium concentration of 115 to <130 mEq/L, and the primary endpoint was again change in baseline serum sodium concentration AUC. As occurred with intravenous conivaptan, the increase in AUC was significantly greater with 40 mg (2-fold) or 80 mg (2.5-fold) of conivaptan than with placebo. Secondary endpoints were the same as in the prior study and also demonstrated similar results. Specifically, the median time to achieve a 4 mEq/L or greater increase from baseline in serum sodium concentration was significantly less with conivaptan (27 h with 40 mg and 12 h with 80 mg) than with placebo (72 h). Second, this 4 mEq/L increase in sodium concentration was maintained significantly longer with 80 mg of conivaptan (88.8 h) than with placebo (46.5 h), although not with 40 mg of conivaptan (69.8 h) versus placebo. A third measure, mean change from baseline to end of treatment of serum sodium concentration was also statistically significant for 80 mg of conivaptan (8.2 mEq/L) versus placebo (3.4 mEq/L), but again not for 40 mg of conivaptan (6.4 mEq/L) versus placebo. Finally, normalization of serum sodium concentration (≥135 mEq/L) or a minimum increase of 6 mEq/L was achieved in 82% of patients receiving 80 mg of conivaptan as compared with 48% of patients receiving placebo, a difference that was statistically significant. The comparison of 40 mg of conivaptan (71% of patients meeting criteria) with placebo again did not meet statistical significance. The above findings suggest that oral conivaptan is also effective in achieving normalization or improvement of serum sodium concentration but may require a higher dose, a finding that correlates with the known bioavailability of the drug. The most common adverse events in patients receiving conivaptan included headache, hypotension, postural hypotension, nausea, and constipation and occurred similarly in the placebo and conivaptan groups. Conivaptan was nevertheless generally well tolerated.

Conivaptan received Food and Drug Administration (FDA) approval for short-term (not to exceed 4 days) in-hospital parenteral use in 2005 [4, 11]. It was originally approved for treatment of hyponatremia in euvolemic patients, but hypervolemic hyponatremia was subsequently added to its indications. Oral conivaptan, as with all of the vaptans, is a substrate of cytochrome (CYP) P450 3A4. Conivaptan appears to be the most potent inhibitor of this microsomal enzyme among this class of drugs. Therefore, there is

potential for serious interactions with a number of other drugs, including some chemotherapeutic agents, calcium channel blockers, 3-hydroxy-3-methyl-glutaryl-coenzyme A reductase inhibitors, benzodiazepines, and immunosuppressants, as well as amiodarone, digoxin, and warfarin. Therefore, conivaptan, in spite of oral efficacy, has been limited to parenteral use to date. Some of the other vaptans appear to have fewer CYP P450 3A4 interactions and still offer the prospect of oral use. Trials are currently underway to develop oral formulations of these agents.

Tolvaptan (OPC-41061), another member os this class of drugs, represents an N-substituted member of the benzazepine family [13, 15]. Tolvaptan has 30 times greater selectivity for the V2 receptor than for the V1a receptor and displays linear pharmacokinetics. The oral formulation is rapidly absorbed, reaching peak plasma concentrations in 2–3 h. It has a half-life of 6–8 h, with clearance decreased by 87% when administered with ketoconazole. Maximum serum concentrations are observed to be significantly higher in patients with heart failure after a single dose (average maximum concentration of 374 and 418 ng/mL after a single dose of 30 and 90 mg, respectively, in healthy subjects; 460 and 723 ng/mL in subjects with heart failure at the same doses). There are no significant interactions with amiodarone or warfarin.

Tolvaptan was considered as a possible agent for correction of water and electrolyte balance, particularly in patients with heart failure because of its V2 receptor antagonism [19]. The first prospective, randomized, double-blind, placebo-controlled trial to look at the effects of tolvaptan in this patient population was the ACTIV (Acute and Chronic Therapeutic Impact of a Vasopressin Antagonist in Congestive Heart Failure) trial [20]. Effects attributable to activation at the V2 receptor had previously been noted to occur at lower concentrations of ADH than those potentiated by the V1 receptors [21]. Inhibition of the ADH pathway at the level of the V2 receptor was hypothesized to result in a pure water diuresis, without associated decrease in electrolytes and without triggering of neurohumoral cascades seen with loop diuretics. The primary focus of the study was the evaluation of the diuretic potential of tolvaptan, as assessed by body weight (as a marker of fluid volume), edema, serum sodium, serum potassium, and renal function [20]. Patients with New York Heart Association (NYHA) class III or IV heart failure, left ventricular ejection fraction of less than 40% within the preceding 12 months, and at least two signs of heart failure were randomly assigned to receive either tolvaptan or placebo, in addition to standard heart failure regimens, including diuretics, for up to 10 days of hospitalization, then for 7 weeks following discharge. The endpoints were a change in body weight at 24 h of hospitalization for inpatients and clinically worsened heart failure for outpatients.

Patients receiving tolvaptan had a significant decrease in body weight at 24 h compared with patients receiving placebo, a response that was independent of both dose and left ventricular ejection fraction. Although there was no further decrease in body weight throughout the study period, the initial loss was maintained in the majority of patients. Tolvaptan also provoked dose-dependent increased production of dilute urine, an effect only assessed on the first day of therapy, and edema was improved. Serum potassium levels and renal function were unchanged. The effect of tolvaptan on serum sodium was interesting and somewhat surprising. Tolvaptan was expected to produce a pure water diuresis, but an increase in total sodium excretion was demonstrated, likely attributable to the increase in urine volume and flow. Patients were also noted to increase their fluid intake during administration of tolvaptan. Nevertheless, there was a net decrease in fluid balance at 24 h and a decrease in urine osmolality. In the final analysis, serum sodium normalized in patients with hyponatremia, and even though the effect on sodium waned over the course of the study, levels remained in the normal range for the majority of patients. In comparison, hyponatremia persisted or worsened in patients receiving placebo. Patients who had normal serum sodium levels at the start of the study and who received tolvaptan were observed to have a transient elevation in sodium levels that resolved within 3 weeks.

The ACTIV trial offered some optimistic findings for the treatment of heart failure using tolvaptan. However, a number of questions remained. Patients in the trial were noted to have a decreased response to therapy in terms of body weight and sodium normalization. Because monitoring only continued for 7 weeks after hospital discharge, it is unknown what will be the response to treatment for a more extended period. This question was of particular importance, given early studies of these compounds that demonstrated agonist activity with prolonged administration in animal models. Also, no neurohumoral activation was observed in studies of tolvaptan in animals and healthy subjects, but it was unknown if these same results would be observed in patients with heart failure or in other pathological states. In the relatively short time period of this trial, quality of life was not determined to be different in tolvaptan-treated patients versus those receiving placebo. Ultimately, given the significance of hyponatremia and neurohumoral activation as risk factors for mortality in patients with heart failure, longer studies assessing outcomes in patients receiving tolvaptan were warranted.

The EVEREST (Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study with Tolvaptan) trial sought to answer some of these questions raised by the ACTIV trial [22]. EVEREST, a large international prospective, randomized, double-blind, placebo-controlled trial, looked at longer-term outcomes in patients with heart failure in whom tolvaptan administration was initiated within 48 h of onset of symptoms of decompensation. The study enrolled 4133 patients who were randomized to receive either oral tolvaptan 30 mg/day (2072 patients) or placebo (2061 patients) for a minimum of 60 days, along with a standard regimen of heart failure medications, including diuretics, as deemed appropriate by their treating physician. The trial overall comprised two short-term studies that looked at the effects of tolvaptan on clinical status and symptoms, as well as an outcome study that evaluated all patients randomized to the short-term studies with regard to both short- and long-term outcomes. The primary endpoints for the outcome study were all-cause mortality and the composite of cardiovascular death or hospitalization for heart failure. Consistent with the findings of the ACTIV trial, patients receiving tolvaptan were observed to have significant improvement in signs and symptoms of heart failure compared with placebo in the early phase of the study. Dyspnea and body weight improved at day 1, and the latter was maintained well beyond hospitalization. Likewise, edema improved from day 1 throughout postdischarge week 4. Serum sodium concentration increased in patients with baseline hyponatremia (sodium less than 134 mEq/L), an effect that was also maintained throughout 40 weeks of treatment. Serum urea nitrogen levels decreased in patients receiving tolvaptan as compared with placebo, with little effect on serum creatinine levels, thus supporting the previously observed finding of stable renal hemodynamics in patients receiving tolvaptan. Although several domains of quality of life as measured by the Kansas City Cardiomyopathy Questionnaire (KCCQ) improved significantly, a number of them (clinical summary, physical limitation, total symptoms, symptom frequency, symptom burden, symptom stability, and self-efficacy) did not. Furthermore, the overall quality-of-life score did not show a statistically significant difference compared with placebo. Of the adverse events reported, only thirst occurred with significantly increased frequency in the tolvaptan group. Dry mouth was also more common in the tolvaptan group, as was hypernatremia, but the occurrence of renal failure and hypotension was similar between the tolvaptan and placebo groups.

The scope of this study extended beyond that of the ACTIV trial with the analysis of long-term outcomes in patients receiving tolvaptan. While long-term administration of tolvaptan did not prove to be inferior to placebo with respect to mortality, it also did not demonstrate any favorable effect on all-cause mortality, cardiovascular mortality, or hospitalization for decompensated heart failure. Therefore, tolvaptan, via V2 receptor antagonism, may have utility in the acute setting of worsening heart failure for safely promoting fluid removal, without renal or electrolyte compromise, but does not thus far demonstrate efficacy in the reduction of mortality. There was a relatively high rate of discontinuance of the study drug, which may have diluted the findings of a positive effect on outcome. Also, the question of benefit in a subgroup of patients with hyponatremia is still not clearly answered since in this study, as with the ACTIV trial, few patients met the criterion for severe hyponatremia. This specific question has been addressed in two recent studies, discussed below.

The Study of Ascending Levels of Tolvaptan in Hyponatremia 1 and 2 (SALT-1 and SALT-2) were identical (for purposes of reproducibility and comparability), randomized, double-blind, and placebo-controlled studies looking at the effects of tolvaptan in the treatment of hypervolemic or euvolemic hyponatremia secondary to chronic heart failure, cirrhosis, or SIADH [23]. Unlike previous studies, while initiated in a hospital setting, the bulk of the data was collected on an outpatient basis. All patients included had a serum sodium concentration of less than 135 mmol/L and were stratified as having either mild (serum sodium of 130–135 mmol/L) or marked (serum sodium <130 mmol/L) hyponatremia. Patients with a serum sodium concentration of less than 120 mmol/L with associated neurologic impairment were excluded from the study. A distinction was also made between patients who had heart-failure-associated hyponatremia and those who did not. The two primary endpoints of the study were the change in average area under the curve for the serum sodium concentration from baseline to day 4 and from baseline to day 30.

At the conclusion of the study, patients receiving tolvaptan demonstrated a significantly increased area under the curve for serum sodium concentration as compared with placebo. This result was observed within 8 h of administration of the first dose of study drugs, as well as at all subsequent visits throughout the study. Furthermore, these results were achieved more quickly in the tolvaptan-treated group and were maintained across subgroups independent of whether the hyponatremia was mild or marked at baseline. Thus, a significantly greater number of patients receiving tolvaptan had normal serum sodium levels when assessed on day 4 and on day 30 than did patients receiving a placebo. Only four patients given tolvaptan achieved undesirably

rapid rates of sodium correction, and only four patients exceeded 146 mmol/L of sodium, the predefined criterion for a potentially serious elevation of sodium concentration. Less fluid restriction appeared to be required in patients receiving tolvaptan than in those receiving placebo, particularly in cases of marked hyponatremia. Finally, patients receiving tolvaptan scored higher than patients receiving placebo on the Mental Component Summary of the SF-12 Health Survey, reaching statistical significance in the combined analysis and in the SALT-1 analysis, although not in isolated SALT-2 analysis. Again, patients in the combined subgroup with marked hyponatremia showed improved scores of statistical significance. As had been seen in other studies of tolvaptan, thirst and dry mouth were the most common adverse events, while other adverse events, including death, had a similar incidence in both the tolvaptan and placebo groups. In the 7 days of follow-up, during which time the study drug was discontinued, hyponatremia recurred in parallel between the tolvaptan- and placebo-treated groups. These studies suggest that antagonism of the V2 receptor with tolvaptan is effective in the short term for treating hyponatremia independent of etiology. Tolvaptan was officially approved for use by the FDA in 2009.

As discussed previously, hyponatremia has been demonstrated to be an independent risk factor for mortality in patients with heart failure, cirrhoses, and neurologic disease. In addition, hyponatremia is itself a cause of subtle neurologic impairment, which confers a subsequent fall risk. Thus, correction of hyponatremia might plausibly reduce associated morbidity and offer a survival benefit. Studies to determine that possibility remain to be done. Recent trials, in addition to those discussed here, offer cause for optimism in this regard.

## 2 RENIN–ANGIOTENSIN SYSTEM

The classical model of the renin–angiotensin system (RAS), more specifically called the systemic RAS, comprises several peptides that work in concert to maintain arterial blood pressure and blood volume [1]. The systemic RAS, particularly angiotensin II, is rapidly acting and serves more in a compensatory fashion in the acute setting, such as hemorrhage, than in response to moment-by-moment fluctuations of hemodynamics. Renin, a proteolytic enzyme produced by the cells of the juxtaglomerular apparatus, is released in response to decreased pressure and stretch at renal baroreceptors, and in response to direct sympathetic outflow to the juxtaglomerular apparatus, such as would occur in the setting of low blood pressure or blood volume. Renin has an indirect influence on hemodynamics, acting to set into motion a cascade of events that begins with renin's cleavage of angiotensinogen to angiotensin I. Angiotensinogen is a proenzyme synthesized in the liver and readily available for conversion once renin enters the circulation. Angiotensin I is a decapeptide (angiotensin 1–10) and, like renin, has minimal direct biological activity, but is the precursor of angiotensin II, a key mediator in the regulation of cardiac and renal hemodynamics.

Angiotensin II is an octapeptide. Again referring to the classical model, the conversion of angiotensin I to angiotensin II is effected by the angiotensin-converting enzyme, which is produced predominantly by vascular endothelium of the pulmonary vasculature. Like angiotensin I, ACE is readily available once renin release has been stimulated. Angiotensin II functions directly as a potent vasoconstrictor in renal, cutaneous, and splanchnic vascular beds by activating angiotensin II type 1 (AT1) receptors, leading to an increase in systemic vascular resistance and thus raising blood pressure. (Importantly, AT1 receptors are absent or sparse in the coronary, cerebral, and pulmonary vasculature, thus protecting these systems from the potentially deleterious effects of increased vascular resistance and elevated blood pressure.) ACE also plays a role in bradykinin inactivation. Bradykinin is itself a vasodilator and also promotes synthesis of prostaglandins, another vasodilator. Therefore, in the setting of ACE activity, two pathways converge to produce increased systemic vascular resistance and thus increase blood pressure. First, ACE catalyzes the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor. Second, by inactivating bradykinin, ACE interrupts a pathway that would otherwise decrease peripheral vascular resistance and thereby reduce blood pressure. Angiotensin II acts directly and indirectly to increase intravascular volume. Directly, it leads to enhanced sodium reabsorption in the renal proximal tubule via activation of AT1 receptors. It functions indirectly through two mechanisms. The first of these is stimulation of hypothalamic thirst centers, with consequent increased fluid intake and thus increased blood volume. Second, it promotes production of aldosterone, a mineralocorticoid hormone, in the adrenal cortex. Aldosterone in turn leads to enhanced sodium reabsorption in the renal collecting duct, with associated increased reabsorption of water.

It is tempting to present only this classical model of the RAS, but to do so would forfeit the opportunity to review newer data regarding additional mediators, as well as novel actions of the well-known players, of this system. This new knowledge permits an occasion to discuss the evolving understanding of the mechanisms of action of commonly used inhibitors of the RAS, to present new drugs that are proving beneficial in thwart-

ing the harmful effects of the system, and to consider tantalizing prospects regarding potential therapeutic targets.

Newer and rapidly evolving data clearly indicate that the systemic RAS is much more complex and exerts far greater influence than previously realized. Data from human and animal studies demonstrate that not only does each component in the system—renin, angiotensin, and aldosterone—have more diverse actions than described in the classical model of the system, but there are in fact many more players, some of which are proving to have relevance in the pathologies previously attributed to the classical model alone. Indeed, their role in pathology can be attributed in large part to the newfound realization that there are tissue-specific and intracellular renin–angiotensin systems (RAS) at work, and the interrelationship of the systemic and local systems, as well as of the individual elements of these systems, are far more complex and integrated than the classical model would suggest [24–27]. Angiotensin I, despite its lack of biological activity, can be considered the hub of the axis. It is the actions of various enzymes, not just ACE, on angiotensin I that directly or ultimately lead to the several known biologically active constituents of the RAS [24–26, 28–30]. To begin, as described above, cleavage by ACE of two amino acids from angiotensin I yields angiotensin II. However, it is now known that angiotensin II is the product not only of ACE activity but of at least one additional enzyme, chymase. The resultant peptide, angiotensin II, is identical to that produced by ACE. In addition, angiotensin I is not limited to conversion to angiotensin II. Rather, a third enzyme, ACE-2, cleaves a single amino acid from angiotensin I to produce angiotensin 1-9. To better understand the newer paradigm of the RAS as represented in Figure 1, the fate and function of each of these and succeeding components will be considered briefly.

The vasoconstrictor and salt- and water-retaining functions of systemic angiotensin II are well known and have been described previously. Intracellular and local renin–angiotensin systems have been identified in a multitude of tissues, including reproductive, hematologic, cardiac, renal, hepatic, enteric, pancreatic, and brain tissue. The effects of local angiotensin II have best

**Figure 1** New paradigm for the renin–angiotensin system.

been described in the vasculature, kidneys, and heart. Angiotensin II is now identified as a significant mediator of inflammation, stimulating the synthesis and activity of such inflammatory modulators as transforming growth factor-ß (TGF-ß) and nuclear factor-κB (NF-κB) [24, 29, 31, 32]. It both stimulates and interacts with reactive oxygen species (ROS), further fueling the production of NF-κB. Angiotensin II's relationship with ROS is important, as some studies demonstrate that even relatively brief exposure to angiotensin II decreases cell viability, likely secondary to oxidative stress. Additionally, angiotensin II can stimulate cellular hypertrophy, proliferation, or apoptosis, depending on the chronicity and level of angiotensin II, as well as the environmental milieu [33]. Acting principally as a cytokine, angiotensin II induces multiple mediators of fibrosis via the AT1 receptor. Further, in a single study, angiotensin II was shown to upregulate 48 stress-related genes [32]. Many of these are genes for heat-shock proteins, but genes for transcription factors and cell-signaling peptides are also represented, as are genes that participate in deoxyribonucleic (DNA) repair and/or replication. While many of these gene products when chronically stimulated have injurious effects, some of them confer a degree of protection by acting as chaperones or antioxidants, as well as by inhibiting apoptosis.

Angiotensin II production by chymase appears to have an effect at the local level [25, 26, 28, 29, 34, 35]. The question of an alternative pathway of angiotensin II production was raised when it was noted that ACE inhibitors (ACEIs) do not completely block the production of angiotensin II at the tissue level [34]. For example, in one study using ACE knockout mice, the level of angiotensin II in the kidneys remained stable in spite of the absence of ACE [25]. This finding was attributable to significant (14-fold) increase in chymase. Local production of angiotensin II in the heart and the vasculature is also thought to be due largely to chymase activity. Furthermore, chymase and ACE have been demonstrated to be differentially expressed in specific cell types and cellular compartments, as well as in the setting of specific pathological conditions. For example, in the normal human kidney, ACE is expressed in mesangial cells, vascular smooth muscle cells, and tubular epithelial cells, whereas chymase, while also expressed in mesangial cells and vascular smooth muscle cells, is not expressed at all in tubular epithelial cells [34].

Angiotensin II, whether produced by ACE or chymase, can be further metabolized to angiotensin III or even angiotensin IV [28, 35]. Angiotensin III functions similarly to angiotensin II, causing vasoconstriction and stimulating aldosterone secretion [28]. However, angiotensin III is less potent than angiotensin II, and it may participate in blood pressure regulation

by acting centrally. Also like angiotensin II, angiotensin III may stimulate protection of TGF-ß and other growth factors and may also participate in inflammatory processes by acting as a chemoattractant for polymorphonuclear cells. Some studies suggest that angiotensin IV has vasodilatory properties. Also, like angiotensin II, angiotensin IV appears to stimulate cell proliferation, as demonstrated by studies looking at effects in rat pituitary.

ACE-2 is an 805-amino-acid ACE homolog that is distributed throughout a number of disparate tissues, including the heart, lung, vasculature, kidneys, and gastrointestinal tract [30]. The function of ACE-2 most commonly described is cleavage of angiotensin I to form angiotensin 1-9 [36]. Although angiotensin 1-9 is not well characterized and may have limited biological activity, it can be further metabolized by ACE to form angiotensin 1-7, a highly active product that will be discussed in greater detail. (Note that this conversion can also be accomplished by a neutral endopeptidase) [30]. In addition to these actions, ACE-2 can cleave angiotensin II, again forming angiotensin 1-7. This latter process is believed to be the primary role of ACE-2, based on the very high affinity of ACE-2 for angiotensin II. ACE-2 also has demonstrated interactions with multiple other vasoactive peptides, the most notable of which is the interaction with apelin-13, a powerful inotrope. The products of ACE-2 activity are observed to act primarily as vasodilators. Thus, ACE-2 appears to represent the junction of a counterregulatory arm of the RAS [37].

Angiotensin 1-7, as described above, is the direct product of ACE-2-mediated cleavage of angiotensin II. It can also result from conversion of angiotensin 1-9 by ACE and by direct alteration of angiotensin I by prolylendopeptidase and neutral endopeptidase 24.11 [30]. The first known action of angiotensin 1-7 was stimulation of vasopressin release [38]. More recently, angiotensin 1-7 has been demonstrated to be a highly active peptide with diverse and significant functions, most notably in the cardiovascular system but possibly in the kidney, as well. In direct opposition to the actions of angiotensin II, angiotensin 1-7 has been shown to have both antitrophic and antifibrotic properties [30]. Furthermore, it has been shown to improve cardiac function in both normal and heart failure animal models. Angiotensin 1-7 was also demonstrated in animal models to improve contractile function in postischemic reperfused hearts [39]. It has been shown to have antiarrhythmic properties, as well as to diminish cardiac remodeling, in part by decreasing myocyte hypertrophy and limiting collagen deposition [30]. In the kidney, animal models suggest that angiotensin 1-7 is protective in the setting of concomitant hypertension and diabetes [40]. Benefits of angiotensin 1-7 in the heart and kidney may be effected through modulation of oxidative stress.

Thus, the landscape of the RAS has changed dramatically. There are several new players in the RAS, and likely more to follow, whose functions are just now being elucidated. Furthermore, the commonly known peptides have newly discovered activity that may hold relevance in understanding the pathogenesis and pathophysiology of some diseases. There are already drugs available that interrupt the system at every step of the cascade, including ACEIs, angiotensin receptor blockers (ARBs) and, more recently, renin inhibitors. Furthermore, many of these drugs are proving to have benefits well beyond the reduction of blood pressure and blood volume. Having a more complete understanding of the RAS offers not only some possible explanations for these observed benefits but also may provide further inroads for treatment and prevention of disease.

## 3 ACE INHIBITORS

Development of ACE inhibitors (ACEIs) began in the 1960s with the observation that the venom of the Brazilian pit viper, *Bothrops jararaca*, appeared to exert its toxic effect by causing a massive fall in blood pressure [7, 41]. Research demonstrated that the venom comprises, in particular, proline-rich peptides originally thought to work by enhancing bradykinin-dependent effects, particularly vasodilation [42]. In fact, these elements of the venom were referred to as bradykinin-potentiating peptides. Subsequently, kininase II, a bradykinin inactivator, and ACE were determined to be the same enzyme [7]. The first attempt at developing an antagonist to the converting enzyme, a substance that could mimic the effects of the venom in a controlled manner, yielded teprotide. This nonapeptide, when tested in humans, proved to effectively lower blood pressure in patients with essential hypertension and also displayed favorable effects in heart failure patients. ACE was also noted to cleave a dipeptide from the teprotide precursor molecule. By considering this latter action, as well as the inhibitory effects of teprotide, investigators in the mid- to late 1970s were able to develop the first orally active ACEIs, of which captopril, a metabolite of teprotide, demonstrated the most activity and is still used today.

Twelve of the many ACEIs that have been developed are currently available for use in the United States. They vary in terms of several features, including chemical structure, potency, whether or not the original compound is the active drug or a prodrug, and their pharmacokinetic properties [7]. Structurally, an ACEI can be considered one of three basic types, depending upon

which of the following it contains: (1) a sulfhydryl (captopril and related compounds; only captopril is available in the United States), (2) a dicarboxyl group (enalapril, lisinopril, benazepril, quinapril, ramipril, perindopril, and others), or (3) a phosphorous (fosinopril and related compounds; only fosinopril is available in the United States). While there are no studies clarifying the issue, the chemical differences in these compounds suggest the possibility that patients with a relatively mild allergy to a single ACEI might be expected to have a favorable response to a different agent of the same class. Given the enormous benefits of these agents in appropriately selected patients, a trial of a second agent in allergic patients is worth consideration.

In spite of their differences, all of the ACEIs are comparable in terms of clinical effectiveness and utility [7, 8], with the exception that fosinopril and spirapril are eliminated equally by the kidney and liver, whereas the remainder of the ACEIs is eliminated principally by the kidney [7]. Therefore, in the setting of renal impairment, levels of ACEIs are increased, and dosage should be adjusted accordingly. Another important consideration in administering these drugs is in patients with heart failure or who are sodium depleted. These patients would be expected to have elevated levels of renin, making them hyperresponsive to the hypotensive effects of ACEIs. Therefore, these patients should also be started on a reduced dose of medication and titrated up as needed. Table 1 provides an overview of the characteristics of the commonly used ACEIs.

ACEIs have found utility well beyond their function as antihypertensives, including demonstrated profound benefits in the setting of heart disease and chronic renal disease. As there is such an intricate relationship between heart disease, cardiovascular disease, and renal disease, ACEIs have proven to be an extraordinary tool for managing all of these diseases on many levels. The studies of ACEIs were initiated based on knowledge of the RAS and the observation that this system is aberrantly upregulated in many of these conditions. With knowledge of a new paradigm of the RAS, including its actions at the systemic, local, and intracellular level, some of the effects of ACEIs can be explored in greater detail.

There have been numerous trials studying the effects of ACEIs in heart disease [43–45]. Only a few of them will be discussed here, but, to summarize, almost every study looking at the use of ACEIs in the setting of chronic heart failure, myocardial infarction, coronary artery disease, and prophylaxis in patients at high risk for cardiovascular disease have shown a survival benefit. In one of the earliest trials to study the effects of ACEIs on mortality in patients with heart failure (CONSENSUS—Cooperative North Scandinavian Enalapril Survival Study), patients with NYHA class IV congestive heart failure who received enalapril showed a significant decrease in mortality [40, 31, and 27% at 6 months, 1 year, and the end of the study (20 months), respectively] compared with patients who received placebo [46]. Furthermore, due to improvement in symptoms, a significant number of patients were reclassified as having a less severe degree of heart failure in accordance with NYHA standards, suggesting a regression of disease. Consistent with that impression, heart size was reduced in the patients receiving enalapril, and less of the other standard heart failure medications were required in the setting of enalapril administration.

Another study (SOLVD—Studies of Left Ventricular Dysfunction) demonstrated a decreased incidence of heart failure in patients with left ventricular dysfunction when treated with enalapril versus placebo [47]. Additionally, patients with left ventricular systolic dysfunction and symptomatic heart failure (NYHA class II and III) receiving enalapril demonstrated a significant difference in cardiac function from those receiving placebo at one year. Specifically, while patients receiving placebo experienced worsening of cardiac function, with increased end-systolic and end-diastolic volumes, those receiving enalapril experienced a decrease in both parameters, as well as in left ventricular end-diastolic pressure. When enalapril was continued, end-systolic and end-diastolic volumes returned to baseline but still did not progress to the degree of the placebo group. Importantly, left ventricular volume increased in the placebo group but not in the enalapril group. Treatment effects were attributed to altered cardiac remodeling, as well as sustained decrease in preload and afterload. As discussed in the previous section, the ability of ACEIs to interfere with angiotensin II generation, as well as the consequent inflammation and fibrosis, at the tissue level support the idea of ACEIs preventing the deleterious remodeling that occurs in the setting of cardiac dysfunction.

ACEIs have been proven to be beneficial not only in patients with ventricular dysfunction and heart failure but also in patients after acute myocardial infarction [47, 48]. SOLVD comprised two parallel studies: Patients with evident symptoms of heart failure who were already being treated with standard heart failure drugs were enrolled in the treatment arm of the study, while patients with minimal or no symptoms and not on any drug regimen for heart failure were enrolled in the prevention arm. Myocardial infarction was a secondary endpoint of the studies (the primary endpoints were mortality and hospital admission for heart failure). In both the treatment and prevention trials, the overall risk of myocardial infarction was reduced similarly (23 and 24%, respectively), with data suggesting that the effect

**TABLE 1 Features of Some Commonly Used ACEIs**

| Drug | Absorption | Bioavailability | Time to Peak Plasma Concentration | Clearance | Half-life | Oral Dose | Comments |
|---|---|---|---|---|---|---|---|
| Captopril | Rapid | 75%; ↓ by 25–35% by food | ≤1 h | Urine; 40–50% intact | 2 h | 6.25–150 mg, 2–3x daily | |
| Enalapril (prodrug) | Rapid | 60%; not ↓ by food | Prodrug: ≤1 h; metabolite: 3–4 h | Urine; intact and metabolite | Prodrug: 1.3 h; metabolite: 11 h | 2.5–40 mg daily | |
| Lisinopril | Slow, variable | 30%; not ↓ by food | 7 h | Urine; intact | 12 h | 5–40 mg daily | Does not accumulate in tissues. |
| Benazepril (prodrug) | Rapid | 37%; slightly ↓ by food | Prodrug: 0.5–1 h; metabolite: 1–2 h | Urine and bile | 10–11 h | 5–80 mg daily | Accumulates in lung tissue |
| Fosinopril (prodrug) | Slow | 36%; rate, not extent, ↓ by food | 3 h | Urine and bile | 11.5 h | 10–80 mg daily; 5 mg daily if $Na^+$ or water depletion, or renal failure | Clearance not significantly altered by renal impairment. |
| Quinapril (prodrug) | Rapid | 60%; rate, not extent, ↓ by food | Prodrug: 1 h, may be delayed after food; metabolite: 2 h | Urine 61%; feces 37% | Initial = 2 h; terminal half-life of 25 h due to high-affinity binding to ACE in tissues | 5–80 mg daily | Conversion from prodrug to metabolite decreased in patients with impaired liver function. |
| Ramipril (prodrug) | Rapid | 50–60%; rate, not extent, ↓ by food | Prodrug: 1 h; metabolite: 3 h | Urine | Initial: 2–4h; intermediate: 9–18 h; terminal: >50 h | 1.25–20 mg daily | Triphasic elimination kinetics; initial—distribution to all tissues; intermediate—clearance of free metabolite from plasma; terminal—dissociation from tissue. |

*Source*: Adapted from information in ref. 7.

regarding nonfatal myocardial infarction was even greater (29%). The difference in effect between enalapril and placebo was not statistically significant at 6 months, but the difference between the two groups (enalapril versus placebo) increased significantly from that point on.

Very positive effects of ACEIs on the kidney have also been reported [49]. Hypertension is one of the two most common causes of chronic kidney disease [50]. Conversely, kidney disease can cause hypertension, so blood pressure control is an important objective in preventing the onset and progression of renal disease. Given the mechanism of action of ACEIs, as well as their initial indication as antihypertensives, they have an obvious role in preventing or ameliorating the effects of chronic kidney disease by lowering blood pressure.

Diabetes mellitus is the other of the two most common causes of chronic kidney disease [50]. Patients with diabetes who develop renal impairment typically have an insidious decrement of renal function over time. Some studies suggest that this progression is slowed with administration of antihypertensives of any kind. Other studies found that use of ACEIs specifically slowed the rate of progression of nephropathy in diabetic patients, even if the patients were normotensive at baseline [51]. Equipped with this knowledge, Lewis et al. carried out a landmark trial studying the beneficial effects of ACEIs (captopril, specifically) on renal function, apart from their antihypertensive properties, in patients with diabetes [52]. The primary endpoint of this randomized controlled trial (RTC) was doubling of baseline serum creatinine in patients with insulin-dependent diabetes mellitus, and the major secondary analyses were the length of time to the combined endpoints of death, dialysis, and transplantation, as well as of changes in renal function. Patients receiving captopril had an overall 48% decrease of doubling of serum creatinine as compared with patients receiving placebo. Subgroup analyses reflected a greater reduction in risk correlating with a higher baseline serum creatinine. Similarly, the rate of decline of renal function was significantly slower in the captopril group than in the placebo group. Finally, patients receiving captopril had a 50% decreased risk of the aforementioned secondary combined endpoints of death, dialysis, and transplantation. These results were independent of blood pressure between groups, thus suggesting that the benefits of ACEIs in diabetic nephropathy extend beyond blood pressure control.

A subsequent study looked at the effects of ACEIs in normotensive, type II diabetic patients with microalbuminuria [51]. The purpose of the study was to examine how ACEIs influenced proteinuria and the rate of decline of kidney function in this patient population. Albuminuria, blood pressure, serum creatinine, fasting blood glucose, and glycosylated hemoglobin levels were measured every 3–4 months. Renal function remained stable throughout the 5-year study period in patients receiving enalapril, compared with a 13% decline in renal function in patients receiving placebo. The increase in albuminuria was significantly less in the enalapril group than in the placebo group at the end of 5 years. Furthermore, patients in the albuminuria group experienced a decline in albuminuria in the first year of the study prior to the subsequent increase. Finally, mean blood pressure continued to be stable in the enalapril group for the duration of the study, while blood pressure in the placebo group increased by an average of 5 mmHg by the end of the study. This study was small, with only 94 patients. However, it extended the idea that ACEIs are effective in the growing population of patients with non-insulin-dependent diabetes mellitus (NIDDM), as well as in those with insulin-dependent diabetes mellitus (IDDH). In addition, it suggested the importance of early initiation of ACEIs, even in the absence of hypertension, in patients with even minimal proteinuria. These concepts have been supported by a number of larger studies.

Eventually, clinical trials were conducted to attempt to determine the effectiveness of ACEIs in slowing the rate of progression of nondiabetic renal disease. The REIN (Ramipril Efficacy in Nephropathy) study was one of the first to consider this question, looking specifically at whether an ACEI was more effective in slowing the rate of decline of the glomerular filtration rate (GFR) (the primary endpoint), decreasing proteinuria, and preventing end-stage renal disease in nondiabetic patients when compared with standard treatment regimens for the same population [53]. Patients in the study were randomly assigned to receive either ramipril or placebo after stratification according to baseline proteinuria (<3 g vs. ≥3 g). Standard antihypertensive medications were used to achieve a target diastolic blood pressure <90 mmHg. Not surprisingly, patients with a baseline proteinuria ≥3 g/24 h had significantly greater monthly rate of GFR decline than did those with baseline proteinuria <3 g/24 h. Additionally, the mean monthly rate of GFR decline in the patients with higher baseline proteinuria receiving ramipril was 0.39 mL/min as compared with 0.89 mL/min in patients receiving placebo. These findings from the second interim analysis were so significant that placebo treatment was terminated at that time and ramipril was made available to the patients who had been receiving placebo. These latter patients were subsequently found to have a significant decrease in the rate of decline of renal failure, and those patients continuing on ramipril experienced continued decrease in the rate of decline of

renal function such that it correlated with what was considered essentially normal. Further analyses demonstrated that patients begun on ramipril at the beginning of the study were significantly less likely to progress to end-stage renal disease (ESRD) than those switched to ramipril at the time of the interim analysis. The study continued for the group of patients with lower baseline proteinuria, and patients from this stratum, as with those presenting with higher baseline proteinuria, were significantly less likely to advance to ESRD than were those receiving placebo. This study, like those in patients with diabetes mellitus, strongly suggested that ACEIs are effective in decreasing the rate of decline of renal function in patients with chronic renal insufficiency to an extent not explained simply by blood pressure reduction.

In addition to the benefits enumerated above, ACEIs have been demonstrated to affect a significant reduction in mortality in patients with scleroderma renal crisis [54, 55]. Scleroderma renal crisis (SRC), defined as new-onset severe hypertension with rapidly progressive renal failure, is an uncommon but severe complication of systemic sclerosis, occurring in approximately 5% of patients. At one time, the only definitive treatment available was bilateral nephrectomy. Absent treatment, SRC was once uniformly fatal, usually within months. Prior to the availability of ACEIs specifically, the one-year mortality associated with SRC was 76%, but the administration of high-dose ACEIs has reduced the mortality to less than 15%. SRC appears to occur most commonly in patients with diffuse system sclerosis, and most patients experience SRC within 4 years (median approximately 2.4 years) of onset of symptoms of systemic sclerosis. Patients who are diagnosed early and treated aggressively with ACEIs consistently have the best outcomes, with many requiring no dialysis within the first year, or requiring only temporary dialysis [56]. Furthermore, patients who were continued on ACEIs after resolution of the renal crisis often showed continued improvement in renal function, whereas no patients who discontinued ACEIs demonstrated spontaneous recovery of renal function. Thus, continuation of ACEIs after blood pressure has been controlled, even in the setting of elevation in serum creatinine, is typically warranted. The pathology of SRC is well characterized, with the hallmark being concentric intimal proliferation in small arteries and arterioles, known colloquially as an "onion-skin" lesion. While the pathogenesis is unclear, most patients with SRC are hyperreninemic and display associated hypertrophy of the juxtaglomerular apparatus, and this hyperactivity of the renin–angiotensin–aldosterone axis appears to play a role. Thus, by interrupting this pathway, ACEIs offer an effective means of treating SRC in many patients.

## 4 ANGIOTENSIN II RECEPTOR BLOCKERS

Development of potential inhibitors of the angiotensin II AT1 receptor began in the early 1970s with elucidation of the functional components of the native angiotensin II octapeptide [7, 57]. Early investigations into the effects of angiotensin II on sympathetic nerves and smooth muscle cells revealed that, while the free C-terminal $CO_2H$ was necessary for both uptake into nerve terminals as well as the pressor response in muscle, an aromatic ring on the phenylalanine at position 8 was required only for the pressor response but did not affect uptake [58]. Therefore, a number of 8-substituted peptide analogs of angiotensin II were created in an attempt to find one or more that could antagonize the pressor effects of angiotensin II in vivo [59]. While a number of these analogs, including saralasin [60–62] and 1-sarcosine, 8-isoleucine angiotensin II [63, 64], and others, proved to be powerful inhibitors of angiotensin II, they were not clinically useful. One drawback was their peptide nature, which limited bioavailability and necessitated intravenous administration. More importantly, they exhibited considerable agonist activity in some patients, making them nonviable for clinical application.

In order to circumvent the issue of bioavailability, the next phase involved development of nonpeptide angiotensin II analogs [65]. The first of these to demonstrate therapeutic promise were S8307 and S8308 and related compounds, all of which were benzylimidazoles [7, 57, 66]. Unlike the previously developed peptides, these compounds were both orally bioavailable and selective for the angiotensin II receptor. However, they displayed only weak receptor antagonism and so were not an option for clinical use. Nevertheless, the structure of these compounds provided a chemical lead for further attempts at development of an effective angiotensin inhibitor.

Researchers first noted that the carboxylic acid moiety at the 2′ position of the biphenyl in the newer compounds was required for binding affinity to the angiotensin II receptor but conferred only limited bioavailability [67]. A number of modified compounds were created with substitution of acidic isosteres with varying degrees of lipophilicity and metabolic stability. The result of these efforts was the development of the first orally bioavailable, selective, and potent angiotensin II receptor blocker (ARB), DuP753, now called losartan. Losartan is a biphenylmethyl derivative, wherein a tetrazole ring is substituted for the original carboxylic acid at the 2′ position. Losartan received approval from the U.S. FDA in 1995, and a number of related compounds quickly followed [7]. The others are also biphenylmethyl derivatives, with the

exception of eprosartan, a thienylmethylacrylic acid derivative.

In contrast to the original peptide analogs, these compounds have no agonist activity, regardless of dose [7]. All of the clinically available ARBs exhibit high-affinity binding of the angiotensin receptor, with selectivity for the AT1 receptor being approximately 10,000 times greater than for the AT2 receptor. Among the biphenylmethyl derivatives, candesartan is reported to have the highest affinity of this class, followed by irbesartan, then telmisartan [7, 68]. Valsartan and the active metabolite of losartan (EXP3174) are essentially equal in affinity to telmisartan. Losartan has the lowest affinity of the group. A separate study demonstrated telmisartan to have the highest binding affinity, followed by olmesartan, then candesartan, and finally EXP3174, valsartan, and losartan [69]. Further details of the pharmacological characteristics of some of the commonly used ARBs are discussed below. All of the ARBs are competitive inhibitors of angiotensin II at the AT1 receptor, but based on binding affinity they can be further categorized as being surmountable or insurmountable [7, 69, 70]. That is, the dose–response curve of angiotensin II, while shifted to the right in the presence of any ARB, is not shifted in parallel when they are compared. Thus, in the setting of surmountable antagonism, as occurs with losartan, the maximal effect of the native compound (angiotensin II, in this case) can overcome the antagonism of the drug. Conversely, telmisartan and candesartan exhibit insurmountable antagonism. After efficient and tight binding to the AT1 receptor, telmisartan dissociates very slowly, and it is this slow dissociation that likely largely accounts for the insurmountable antagonism of telmisartan, as well as its long-lasting therapeutic effects.

Losartan, the first of the ARBs, has a bioavailability of less than 50%, as is generally the case with members of this class [7]. Losartan is partially metabolized to EXP 3174, a 5-carboxylic acid, and other metabolites by CYP2C9 and 3A4. EXP 3174 is the only known active metabolite and is a more potent antagonist of the angiotensin II AT1 receptor than is losartan itself. Peak plasma levels of losartan are reached within approximately 1 h, while those of EXP 3174 are reached in 3 h. The half-lives of losartan and EXP 3174 are 2.4 h and 6–9 h, respectively. Even though losartan and EXP 3174 are both hepatically and renally cleared, clearance is affected only by hepatic, but not renal, insufficiency. The standard dose of losartan is 25–100 mg, given as a single or divided dose.

Candesartan cilexetil is a prodrug [7]. The active metabolite, candesartan, is created by hydrolysis in the gastrointestinal tract, with subsequent absorption. The half-life of candesartan is 9 h, with peak plasma levels achieved within 3–4 h. Candesartan undergoes both renal (33%) and biliary (66%) clearance, but conversely to losartan, clearance is affected by renal, but not mild-to-moderate hepatic, insufficiency. Candesartan is dosed between 4 and 32 mg daily, given as a single or divided dose.

Eprosartan is distinguished pharmacologically by being a thienylmethylacrylic acid derivative [7]. The bioavailability is approximately 13% [71]. Eprosartan reaches peak plasma levels in 1–2 h, with a terminal half-life of 5–9 h. It undergoes partial metabolism to its glucuronide conjugate. Both eprosartan and its metabolite undergo renal and biliary clearance, and both renal and hepatic insufficiency alter the rate of clearance. The total daily dose of eprosartan is 400–800 mg, given in one or two doses. Eprosartan appears to have a unique characteristic in that, in animal models, it inhibits sympathetic outflow-induced pressor responses [72]. Thus, eprosartan acts both directly and indirectly to inhibit the actions of angiotensin II, perhaps affording it an advantage in the antihypertensive arena.

Irbesartan, like eprosartan, is partially metabolized to its glucuronide conjugate by cytochrome P450 2C9 [7]. Oral bioavailability is approximately 60–80% and is unaffected by food [73, 74]. The half-life is 11–15 h, although peak plasma levels are achieved within 1.5–2 h. The steady-state volume of distribution of irbesartan is 53–93 L. Twenty percent of the clearance of irbesartan is renal, while the remaining 80% is biliary, with less than 10% of intact drug is excreted in the urine and less than 30% in the feces. Neither renal nor mild-to-moderate hepatic insufficiency alters clearance. Irbesartan is administered as a single daily dose of 150–300 mg.

Telmisartan reaches peak plasma concentrations in 0.5–1 h, and its half-life of 24 h is the longest of any of the ARBs to date [7]. As touched on previously, telmisartan has an extended dissociation half-life of 75 min, which is nearly five times longer than that of angiotensin II, and which largely accounts for its long duration of action [70]. Unlike the other ARBs discussed, telmisartan is excreted primarily as the intact drug via biliary secretion. Clearance is affected by any degree of hepatic insufficiency. The dose of telmisartan is 40–80 mg, given once a day.

Valsartan has a half-life of 9 h, reaching peak plasma concentrations in 2–4 h [7]. Valsartan should be taken on an empty stomach, as food significantly decreases the absorption of the drug. Seventy percent of the clearance of valsartan is via a hepatic mechanism, and clearance is affected by hepatic insufficiency. The remainder is renally cleared, but no dosage adjustment is required for renal insufficiency. Valsartan is given as a once-daily dose of 80–320 mg.

There are numerous studies investigating the potential benefits of the ARBs in comparison with placebo,

as well as with other antihypertensives. Still others consider ARBs in combination with other agents. While space does not permit a detailed discussion of all of these studies or even of the questions they address, several of them will be presented in order to highlight a few of the relevant findings.

Until the development of ACEIs and ARBs, the most effective intervention for reducing the incidence of cardiovascular morbidity and mortality in patients with hypertension was a regimen of ß-blockers and diuretics. Furthermore, left ventricular hypertrophy (LVH) is a known independent risk factor for cardiovascular morbidity and mortality. The LIFE (Losartan Intervention for Endpoint reduction in hypertension) study sought to determine if ARBs could improve left ventricular hypertrophy and thereby reduce the incidence of cardiovascular morbidity and death compared with atenolol, a ß-blocker [75, 76]. In this randomized, double-blind, parallel-group trial, over 9000 patients with seated systolic blood pressures of 160–220 mmHg and diastolic blood pressures of 95–115 mmHg, as well as LVH, were assigned to receive either losartan or atenolol and were followed for a minimum of 4 years, or until 1040 patients had a primary cardiovascular event, defined as death, myocardial infarction, or stroke. Although blood pressure reduction was significant and similar in the two groups, significantly fewer patients in the losartan group experienced an event defined by the primary endpoint (508 patients in the losartan group versus 588 in the atenolol group, relative risk 0.87). This difference is largely attributable to a significantly lower incidence of fatal and nonfatal stroke—an impressive 25% adjusted risk reduction—in the losartan group. The incidence of myocardial infarction did not differ significantly between the two groups. Notably, LVH-defining voltage indices as defined by both the Cornell and Sokolow-Lyon criteria were significantly reduced in the losartan group as compared with the atenolol group. Another interesting discovery was a 25% reduction in the risk of new-onset diabetes in the patients receiving losartan. This is similar to findings in studies of ACEIs and is a theme that recurs in studies of others of the ARBs. The effect may be attributable to modulation of insulin resistance.

Another arm of the LIFE study considered the role of losartan in the prevention of cardiovascular morbidity and mortality in patients with diabetes [77]. Of the original study population, 1195 patients with diabetes in addition to hypertension and electrocardiographic evidence of LVH were randomly assigned to receive either losartan or atenolol after a placebo run-in period. As in the main study, the primary composite endpoint was cardiovascular morbidity and mortality, comprising cardiovascular death, stroke, or myocardial infarction. Not surprisingly, blood pressure reduction and control were comparable in the two groups. The relative risk of the composite endpoint in the losartan group was only 76% of that in the atenolol group, a significant difference, and all-cause mortality was also significantly lower in the losartan group (relative risk 0.61). In this subgroup study, the reduction in risk of composite endpoints was predominantly attributable to a reduction in cardiovascular mortality, as the difference in incidence of stroke and myocardial infarction between the two groups was nonsignificant. Also, with regard to secondary endpoints, the incidence of hospital admissions for heart failure was significantly lower in the losartan group (adjusted hazard ration 0.59). In both the principal study and in this subgroup, the benefits in the losartan group were evidently greater than those attributable to blood pressure control alone, as both groups had similar reductions in and maintenance of blood pressure throughout the study.

Another study to evaluate the potential benefits of ARBs with respect to cardiovascular disease was the Valsartan Antihypertensive Long-term Use Evaluation (VALUE) study [78, 79]. Investigators hypothesized that, given the known multiple deleterious effects of angiotensin II, an ARB would provide greater overall cardiovascular benefit than a calcium-channel blocker in patients with equivalent blood pressure control and high cardiovascular risk. The primary endpoint of the VALUE study was composite morbidity and mortality secondary to cardiac events. The VALUE study was an international, double-blind, prospective, parallel-group trial that randomized 15,314 patients 50 years of age or older with hypertension (treated or untreated) and a high risk of cardiovascular events to begin treatment with either valsartan or amlodipine. Of the patients randomized, 15,245 were considered in the final analysis. The study followed a carefully proscribed algorithm of medication selection and administration, wherein patients were started on a low-dose of either valsartan or amlodipine, and any necessary increase of study drug or addition of medications was done at monthly intervals in a specified sequence [i.e., begin with low-dose study drug, increase the study drug, add a diuretic (hydrochlorothiazide), increase the diuretic, add any antihypertensive other than ACEI, another ARB, or calcium antagonist]. A larger proportion of patients taking valsartan required the highest dose of study drug plus hydrochlorothiazide (HCTZ) plus other antihypertensives than did patients receiving amlodipine. The vast majority of patients were on antihypertensives at the start of the study and were rolled over into the study without a washout period. Interestingly, the decrease in blood pressure in the amlodipine group was significantly greater than in the valsartan group at the doses used. This effect was more pronounced in the early part of

the study. There were also fewer events in terms of the primary outcome measure in the amlodipine group, although this finding was statistically nonsignificant. This result may be attributable to the difference in blood pressure lowering between the two study drugs. Although the rates of heart failure admissions and both fatal and nonfatal stroke were similar in the two groups, the other secondary outcomes of myocardial infarction (fatal and nonfatal) and total cardiovascular events were greater with valsartan than with amlodipine. Nevertheless, the rates of all-cause death were not significantly different in the two groups. Importantly, the incidence of new-onset diabetes was significantly less in patients receiving valsartan than in those receiving amlodipine, 13.1 versus 16.4%, respectively.

Like ACEIs, ARBs were considered a promising alternative for treatment of patients with renal disease precisely because of their inhibition of the effects of angiotensin II. Once again, the high incidence of renal disease, as well as the significance of hypertension and cardiovascular risk in patients with diabetes, drove the investigation of the utility of ARBs in thwarting some of the many adverse consequences of diabetic and nondiabetic renal disease [80–84]. The Irbesartan Diabetic Nephropathy Trial (IDNT) sought to determine if an ARB (irbesartan) could prevent the progression of nephropathy independently of blood-pressure-lowering effects to a greater extent than either a calcium-channel blocker (amlodipine) or placebo [85–87]. In the IDNT, 1715 patients with type II diabetes mellitus, hypertension, and at least 900 mg proteinuria were randomized to receive irbesartan, amlodipine, or placebo. Other antihypertensive medications were added as necessary to achieve blood pressures of 135/85 or less. The primary endpoint was a composite of doubling of baseline serum creatinine, end-stage renal disease, and death due to any cause. The findings in the study were striking. Even though blood pressures were comparable in the three groups, and there was no difference in the rate of death due to all causes, the risk of reaching the primary combined endpoint in the irbesartan group was 20% lower than in the placebo group and 23% less than in the amlodipine group. In terms of the individual parameters, doubling of baseline serum creatinine was 33% lower with irbesartan than with placebo, and 37% lower with irbesartan than with amlodipine. Proteinuria was reduced by 33% in the irbesartan group, 6% in the amlodipine group, and 10% in the placebo group, with the relative risk of end-stage renal disease being 23% lower with irbesartan than with either placebo or amlodipine. There was, therefore, demonstrated renoprotection in the setting of type II diabetes-induced nephropathy with use of irbesartan, an effect apparently independent of the antihypertensive actions of this ARB.

The results of another study, the Reduction of Endpoints in NIDDM with the Angiotensin II Receptor Antagonist Losartan (RENAAL) study, very closely mirrored those of the IDNT [88]. This multinational, double-blind trial randomized 1513 patients with type II diabetes mellitus and at least 500 mg of proteinuria to receive either losartan or placebo, as well as additional antihypertensives as necessary to achieve a blood pressure of less than 140/90 mmHg. As with the IDNT, the primary endpoint was a composite of doubling of baseline serum creatinine, progression to end-stage renal disease, or death due to any cause. Patients receiving losartan had a 16% decreased risk of the primary composite endpoints compared with patients receiving placebo. With respect to renal parameters, the risk of doubling of serum creatinine was decreased by 25%, and the risk of end-stage renal disease was reduced by 28%, in patients receiving losartan versus those receiving placebo. The rate of all-cause mortality was not different between the two groups. RENAAL, like IDNT, clearly demonstrated beneficial renoprotective effects with use of an ARB and also showed that these effects extend beyond those attributable to blood pressure reduction alone.

Given the findings described above, ARBs appear to have renoprotective effects beyond those of placebo or calcium-channel blockers. Recall, too, the significant benefits of ACEIs in preventing the progression of renal disease in both diabetic and nondiabetic patients, which have been well documented, as described earlier. However, some studies have suggested an angiotensin II escape mechanism that blunts the long-term efficacy of the ACEIs [89]. Thus, the question was raised whether an ARB might offer greater long-term benefits in the treatment of renal disease. The obvious next step was a head-to-head comparison of these two classes of medications. In a small prospective, open-blind study, 68 Japanese patients with renal insufficiency (creatinine clearance 25–50 mL/min) and hypertension were randomized to receive either an ACEI (benazepril or trandolapril) or an ARB (candesartan or losartan) and were then monitored for changes from baseline GFR over a 5-year treatment period [90]. There was no significant difference between the two groups with respect to this primary endpoint. However, the study also investigated several secondary endpoints, including annual changes in GFR, serum creatinine levels, urinary protein excretion, blood pressure, and the rate of development of end-stage renal disease, and there were several outcomes of note. In particular, absolute decline in GFR in the group treated with ARBs was significantly greater than in patients treated with ACEIs, a difference that did not become apparent until year 3 of the study. In addition, progression to end-stage renal disease with

initiation of dialysis was significantly greater in the ARB group (81.2%) than in the ACEI group (52.7%), a difference that also did not develop until year 3 of the study. Throughout the study, there was no statistically significant difference in blood pressures between the two groups.

The results of the above study were not corroborated in a larger trial, Diabetics Exposed to Telmisartan and Enalapril (DETAIL) trial [22, 91]. This is perhaps due to the small patient population of the former study, as well as bias introduced by single-physician participation and the lack of double blinding. The DETAIL trial was a 5-year, double-blind, double-dummy, randomized study of 250 patients with hypertension and early-stage diabetic renal disease assigned to receive either telmisartan or enalapril and subsequently monitored for changes from baseline GFR (primary endpoint). The study secondarily considered progression to end-stage renal disease, as well as all-cause mortality. Contrary to what was found in the prior study, there was no significant difference in annual decline of GFR between the telmisartan group and the enalapril group. Additionally, all patients in both groups maintained a serum creatinine less than or equal to 200 μmol/L, and none of the patients in either group required dialysis throughout the entire 5-year study period. There were six deaths in each study group, and half of these deaths were cardiovascular in nature. These studies raise an interesting question: Would combination therapy with an ACEI and an ARB be more beneficial than monotherapy for treatment of chronic renal disease? Early studies suggested that this might be the case in select patients, particularly those in whom blood pressure is not controlled and in those in whom urinary protein excretion remains high despite monotherapy [92, 93]. The COOPERATE trial [103] was a randomized controlled trial comparing the effects of losartan, trandolapril, or the combination of the two drugs at equivalent doses in patients with nondiabetic chronic kidney disease. The primary endpoint was a composite of time to doubling of serum creatinine or end-stage renal disease. While this study suggested a benefit with combination therapy, the validity of the results was later questioned and the paper was subsequently retracted. Since then, studies have failed to demonstrate a significant synergistic benefit to using combination ACEI/ARB therapy, and in fact, multiple studies have shown an increased risk of adverse effects associated with combination therapy compared to monotherapy [104, 105]. The ONTARGET study was a large, randomized controlled trial comparing the effects of telmisartan, ramipril, and the combination of both drugs in 25,620 patients with vascular disease or high-risk diabetes [104]. Treatment with the combination of telmisartan and ramipril did not significantly reduce the incidence of cardiovascular disease or death compared to monotherapy and was associated with a significantly increased risk of hypotensive symptoms, syncope, and renal dysfunction. A subsequent report from the same investigators studied the effects of combination therapy versus monotherapy on renal outcomes in a subset of the patients enrolled in the original trial who who had impaired renal function and/or proteinuria [105]. Combination therapy resulted in a greater reduction in proteinuria when compared to monotherapy but was associated with an increased risk of the primary composite outcome of dialysis, doubling of serum creatinine, and death. Given the results of these studies, combination therapy with ACEI and ARB cannot be recommended at this time.

## 5 RENIN INHIBITORS

Thus far in this review, drugs that block the production of angiotensin II and that interfere with the actions of angiotensin II have been discussed. These drugs reflect a logical approach in disease modulation, based on an understanding of the RAS that was described previously. However, some interesting override mechanisms occur with the use of these medications that may explain to a great extent why they do not demonstrate an even greater effect than they do [89]. Recall from the previous discussion that the new understanding is of a local as well as systemic RAS. Tissues express various components of the system, including ACE and AT1 and AT2 receptors, that permit local production and activation of angiotensin II. Notably, however, renin and its precursor molecule, prorenin, are not present in these local systems. Rather, systemic renin produced in the juxtaglomerular apparatus is taken up by tissues and utilized to initiate the ultimate production of angiotensin II. Angiotensin II itself exerts negative feedback on the juxtaglomerular cells via the AT1 receptor, thereby bringing about a reduction in renin and consequently of angiotensin II. In the setting of ACEI or ARB, there is a reactive increase in renin, and to a somewhat lesser extent of prorenin, due to the lack of angiotensin-II-mediated negative feedback. With the rise in plasma renin activity (PRA), there is a resultant increase in the production of angiotensin I. In patients receiving ARBs, there is a corresponding increased production of angiotensin II. In addition, even though ACEIs are expected to prevent the production of angiotensin II, studies have demonstrated that renin levels can rise far enough above baseline during ACEI administration that over time normal or even supranormal levels of angiotensin II are restored, a mechanism known as *angiotensin escape*. Ultimately, then, the beneficial effects of both of these classes of drugs might be blunted or possibly even reversed as a result of misguided compensatory mechanisms.

A search has been underway to find a drug that could overcome these shortcomings of ACEIs and ARBs. The logical point of intervention is at the level of renin production, the rate-limiting compound of the RAS, which would suppress angiotensin I generation and angiotensin II production by ACE, chymase, or other enzymes, and would largely obviate the need for AT1 receptor antagonism. Indeed, the latest weapon in the arsenal of drugs that counter the RAS is a renin inhibitor, aliskiren.

Aliskiren is a low-molecular-weight, nonpeptide compound that exhibits limited (2.6%) oral bioavailability [94]. It is highly selective for the proteolytic binding site of renin, and binding of aliskiren to renin results in a decrease of plasma levels of angiotensin I and angiotensin II. There is a reactive rise in renin levels, but PRA is nevertheless effectively reduced with once-daily dosing. Peak plasma concentrations of aliskiren are reached 2–4 h after oral administration, and a single dose of 160 mg results in plasma concentrations that are 50-fold that of the 50% inhibitory concentration of 0.6 nmol/L. Although peak concentration is significantly reduced when aliskiren is administered with food, the effect on PRA is nevertheless unaffected, so timing of dosing relative to food intake is unnecessary. Clearance of aliskiren is predominantly via the gastrointestinal tract (91%, unchanged), with a mere 0.6% being excreted in the urine, and 1.4% undergoing oxidation. Metabolism does not appear to significantly involve the cytochrome P450 system. Aliskiren has a terminal half-life of 24–40 h due to accumulation in plasma, therefore permitting a dosing interval of 24 h. Studies to date suggest that 150–300 mg administered orally once a day is effective in lowering blood pressure.

In one study, 672 patients with elevated diastolic blood pressures were randomized to receive either aliskiren (150, 300, or 600 mg) or placebo for 8 weeks, followed by a 2-week withdrawal period [95]. Aliskiren demonstrated superiority in lowering both systolic and diastolic blood pressure at all doses in comparison with placebo. The antihypertensive effect was maintained throughout the 2-week withdrawal period. High trough-to-peak ratios permitted smooth and sustained blood pressure lowering. Aliskiren was well tolerated, having adverse event rates comparable to placebo, and there was little discontinuance due to adverse events in the aliskiren group.

A very similar short, multicenter, randomized, double-blind, placebo-controlled, active-comparator trial investigated the efficacy of aliskiren versus irbesartan and placebo for blood pressure reduction in patients with mild-to-moderate hypertension [96]. In the study, 652 patients were randomized to receive aliskiren, irbesartan, or placebo after a 2-week run-in period. Aliskiren at a 150-mg dose was comparable to irbesartan 150 mg with respect to blood pressure lowering, and at doses of 300 and 600 mg was significantly better. Aliskiren at all doses was significantly better than placebo in effecting a reduction in blood pressure. Aliskiren was generally well tolerated.

In a very small double-blind, parallel-group, three-way crossover trial, 18 healthy volunteers on a sodium-restricted (100 mmol/day) diet were randomized to receive two doses of aliskiren (40 mg and then 80 mg, or 160 mg and then 640 mg) plus either placebo or enalapril (20 mg) [97]. The trial was divided into three treatment periods of 8 days each. The treatment periods were separated by 6-day washout periods. Blood pressure was unaffected in this study population. Angiotensin I and angiotensin II were significantly reduced at all levels of aliskiren when compared with placebo. On day 1 and day 8, aliskiren significantly reduced angiotensin II levels within 1 h of oral administration, and this effect was maintained for up to 6 h at all doses except 40 mg. At the highest dose (640 mg) of aliskiren, angiotensin levels were decreased by as much as 89% on day 1. Aliskiren at 160 mg reduced baseline angiotensin II to a degree (56%) comparable to 20 mg of enalapril (57%), whereas 640 mg reduced angiotensin II levels by 76%, a significant difference. At the three lower doses, reduction in PRA and angiotensin I correlated with the reduction in angiotensin II. However, enalapril evoked a 15-fold increase in PRA and angiotensin on days 1 and 8. Note that PRA was increased by as much as 34-fold with the maximum dose of aliskiren. Aldosterone levels in both plasma and urine were decreased with aliskiren (≥80 mg) and enalapril administration. The duration of effect was 6 h with enalapril and as long as 24 h with 640 mg of aliskiren. Sodium excretion was significantly enhanced with aliskiren and enalapril versus placebo, whereas potassium was unaffected. Note that aliskiren was detected in the urine of some subjects throughout the 6-day washout period, suggesting that results were skewed by the prolonged duration of action of aliskiren. As in other studies, aliskiren was well tolerated.

In addition to these promising studies regarding the use of aliskiren as monotherapy in the treatment of hypertension, other studies show beneficial effects of aliskiren used in combination with other antihypertensives [98, 99]. In a study of aliskiren and valsartan, the two drugs used concomitantly afforded significantly greater blood pressure reduction than either drug used alone, but without any increase in adverse events [100]. Likewise, aliskiren plus HCTZ was significantly more effective in reducing blood pressure than either drug used as monotherapy [101]. Furthermore, more patients responded to the dual therapy than to single-drug therapy, and rates of blood pressure control were better in patients receiving combination therapy. An added benefit was the suppression of the rise in PRA that

occurs with HCTZ. Thus aliskiren appears to offer a new alternative in the treatment of hypertension as either monotherapy or in combination with other antihypertensives, with a good safety and tolerability profile [102].

## 1 INTRODUCTION

Osteoarthritis (OA) is one of the most prevalent and chronic diseases affecting the elderly. Its most prominent feature is the progressive destruction of articular cartilage that results in impaired joint motion, severe pain, and, ultimately, disability. Its prevalence and its moderate to severe impact on daily life pose a significant public health problem [1].

Today, a cure for OA remains elusive and the management of OA is largely palliative focusing on the alleviation of symptoms. Current recommendations for the management of OA include a combination of nonpharmacological interventions and pharmacological treatments (Table 1) [2, 3]. Until now, the pharmacological management of OA is dominated by nonsteroidal anti-inflammatory drugs (NSAIDs) and analgesics (mainly paracetamol). Beside these conventional drugs, some new compounds classified as symptomatic slow-acting disease-modifying drugs (SYSADOA) have shown symptomatic efficacy in treating human hip and knee OA. The term SYSADOA covers a range of agents, including glucosamine sulfate (GS), chondroitin sulfate (CS), diacerhein, hyaluronic acid (HA, intra-articularly), and avocado soybean unsaponifiables (ASU). This group of compounds is mainly composed by nutraceuticals, which have been investigated in clinical trials but commonly used as a health food supplement rather than prescribed drugs in Europe and United States. This chapter reviews the available scientific evidence supporting the efficacy, and explaining the mechanism of action, of drugs and nutraceuticals targeting OA.

## 2 OA PATHOPHYSIOLOGY: IDENTIFICATION OF NEW BIOCHEMICAL TARGETS

Osteoarthritis is a heterogeneous group of skeletal disorders characterized by common structural and functional changes in overall joint tissues, including cartilage loss, synovium inflammation, bone sclerosis, cysts, and osteophytes.

The chondrocytes play a critical role in the structural changes in OA cartilage. When chondrocytes experience modification of their environment, they undergo different "phenotype modulations" that result in the expression of a different pattern of genes. The main phenotypic modulations, comprise "dedifferentiation" (characterized by the overexpression of type I collagen), hypertrophy (with the expression of type X collagen, tidemark doubling, and apoptosis as a consequence), recapitulation of development (with the re-expression of type IIa and III collagens), as well as regeneration of mature cartilage (with an overproduction of cartilage-specific matrix macromolecules and cell proliferation) (see a review in [4]). It is unclear if the same chondrocyte may express successively different phenotypes or if chondrocytes from different areas of cartilage express different phenotypes. Nevertheless, it is clear that depending on

their position in relation to the lesion, chondrocytes show different patterns of gene expression. These phenotypic modulations of chondrocytes are usually associated with structural changes observed in OA cartilage, including matrix mineralization, cell clusters, cartilage thickening, and degradation. They may be initiated by mechanical and biochemical factors.

Environmental influences known to affect the regulation of biosynthetic and catabolic activity of chondrocytes have been shown to include soluble factors (oxygen, ions, vitamins, cytokines, hormones, growth, and differenciation factors), extracellular matrix (for a review see [5]), and mechanical stress [6–9]. Among these environmental factors, cytokines play a critical role in OA pathogenesis and constitute a common target for drugs used to treat OA. The inflammatory cytokines, mainly interleukin (IL)-1β, -6, -17, and -18 and the tumor necrosis factor-α (TNF-α) act in synergy to increase synthesis of metalloproteinases (MPs) and to decrease extracellular matrix components synthesis (see also [10–12]). In opposite, insulin-like growth factor (IGF)-1 and transforming growth factor (TGF)-β1, -2, and -3 stimulate extracellular matrix synthesis and counteract the inhibitory effect of IL-1β on extracellular matrix synthesis [13, 14]. Therefore, it is conceivable that, depending on the relative local concentration of IL-1/TNF and IGF/TGF, the net effect on cartilage would be either a reduced or enhanced synthesis of the cartilage matrix components.

### 2.1 Cartilage Repair Reaction

Chondrocytes respond to injuries that disrupt articular cartilage, but that do not extend into subchondral bone, by cell proliferation and an increased synthesis of matrix macromolecules near the injury [15, 16]. This reaction is considered a repair attempt, histologically characterized by cell clusters surrounded by large acellular area but that do not fill the tissue defect [17, 18]. Clustered chondrocytes produce not only large amounts of aggrecan and type II collagen but also molecules such as type I, IIA, III, or X collagens and tenascin, which are usually absent from normal cartilage [19]. This increased metabolic activity of the chondrocytes might be due to better access of chondrocytes to growth factors from the synovial fluid due to fissuring or loosening of the collagen network or due to the damage of the matrix itself.

However, despite this repair attempt, a net loss of cartilage is observed later in the disease process, suggesting that the cartilage repair reaction is transient and inefficient [20]. The explanation for this failure is uncertain and probably involves a network of biochemical and mechanical factors, including the lower resistance of regenerated tissue to mechanical stress, the overproduction of MPs, and reactive oxygen species (ROS) and cell death. Chondrocyte hypertrophy can contribute to the failure of cartilage repair through reduced expression of type II collagen and aggrecan, increased expression of type X collagen, upregulation of matrix MP-13

(MMP-13), and promotion of pathologic calcification [21–23]. It has recently been shown that OA chondrocytes overexpress IL-1 and TNF receptors, whereas transforming growth factor (TGF)β-RII receptor expression is decreased [20, 24, 25]. The modulation of cytokine and growth factor receptor expression focally modifies cell sensitivity and responses to these factors. As a consequence, chondrocytes are more sensitive to IL-1β and TNF-α, two cytokines, stimulating matrix resorption, but less sensitive to TGFβs, factors stimulating matrix formation. It results with an excess of catabolic events and then cartilage loss.

### 2.2 Cartilage Degradation

Cartilage matrix degradation is mainly conducted by mechanical stress, MPs and ROS (see also the reviews in [26, 27]. The mechanical aspect of OA is note discussed in from this review, which is focused on the biochemical aspect of cartilage degradation.

***Proteolytic Cleavage*** Current knowledge indicates an important involvement of MPs, in OA, mainly MMPs and a disintegrin and metalloproteases with thrombospondin motifs (ADAMTS) family [28–31]. In OA, MMPs are secreted by chondrocytes, as well as synovium cells, including fibroblasts and macrophages. MMPs are synthesized as inactive pro-enzymes that are activated in situ by other MMPs, serine and cysteine proteinases [32–34]. Under physiologic conditions, the activity of MMPs is balanced by natural inhibitors that act at different levels of the proteolytic cascade of MMP activation. In contrast, in OA, a shift of this equilibrium leads to excessive matrix degradation [35].

The initial degradation of collagen fibrils depends on the cleavage at the collagenase site located in triple-helical part of the molecule (between residues $Gly^{775}$ and $Leu^{776}$), most likely by collagenase-1 (MMP-1) and collagenase-3 (MMP-13) [36]. Subsequently, denatured collagen fibrils are thought to be further degraded by gelatinases, with gelatinase A (MMP-2) being the major player in OA [37]. A collagenase that may be of particular importance in the degradation of cartilage in pathologic condition is MMP-13, because this MMP is 5- to 10-fold more active on type II collagen than other collagenases [38, 39]. Studies of gene expression in normal and OA cartilage have shown upregulation of MMP-13 in late-stage OA [40].

One of the earliest changes observed in OA is the depletion of aggrecan due to increased proteolytic cleavage of its core protein, mainly by aggrecanases (members of the ADAMTS family) and stromelysin-1 (MMP-3). The aggrecanases (ADAMTS-1, -4, -5, -8, -9, -15) are glutamyl endopeptidases that cleave to the aggrecan core protein at the $Glu^{373}$-$Ala^{374}$ peptide [41], a cleavage site different from the MMP-3 site ($Asn^{341}$-$Ala^{374}$). Shortly after mechanical injury of cartilage explants, ADAMTS-5 and MMP-3 gene expression highly increases, whereas MMP-1 and MMP-13 show little change in expression [42]. In a study comparing gene expression in chondrocytes from patients with early and late-stage OA, Bau et al. [40] have observed that MMP-13 and ADAM-TS4 expression was very low in normal and early degenerative cartilage but increased in late-stage OA, whereas MMP-3 expression was the highest of the gene levels tested and was downregulated in late-stage OA specimens. Altogether these results indicate that, beside aggrecanases, stromelysin-1 plays an important role in the degradation of aggrecan and that collagenases mainly act in the late stage of OA.

***Oxidative Degradation*** Beside the role played by MMPs, there is an expanded body of evidence indicating that ROS are intimately involved in the pathology of OA [27]. The ROS family includes molecules such as hydrogen peroxide ($H_2O_2$), ions such as the hypochlorite ion ($OCl^-$), radicals such as hydroxyl radical ($^{\bullet}OH$), nitric oxide ($^{\bullet}NO$), or superoxide anion ($O_2^-$), which is an ion and a radical at the same time. Chondrocytes are basically able to produce $^{\bullet}NO$ and $O_2^-$, which subsequently generate derivative radicals including peroxynitrite ($ONOO^-$) and $H_2O_2$ [43–46]. $H_2O_2$ can be transformed into $^{\bullet}OH$ through an iron-ion-catalyzed reaction, named the Fenton reaction ($Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{\bullet}OH + OH$-). Both ONOO- and $^{\bullet}OH$ may initiate lipid peroxidation, and the formation of additional long-lived lipidic radicals ($RO^{\bullet}$, $ROO^{\bullet}$). Collectively, chondrocyte lipid peroxidation appears to play a major role in cartilage matrix oxidation and degradation [47]. The overproduction of ROS in pathological cartilage has been indirectly evidenced by the accumulation of lipid peroxidation products (i.e., lipid hydroperoxides and aldehydes) and nitrotyrosine in situ [48]. Recently, we have found elevated nitrated type II collagen peptides in sera of patients with OA, suggesting the formation of peroxynitrite ($ONOO^-$) in OA cartilage [49].

Cellular responses to ROS generation are dependent on the cellular redox status. When the oxidant does not exceed the reducing capacities of cells, ROS are strongly involved in the control of cellular functions including signal transduction. In contrast, in some pathological circumstances when the cellular antioxidant capacity is insufficient to detoxify ROS, oxidative stress may occur that damages not only cellular membranes and nucleic acids but also the extracellular matrix [50–52]. Oxidative stress may also cause cell death and release of cellular content into the extracellular environment [53, 54]. The degradation products and cellular contents including

oxidized molecules may trigger synovial macrophages and fibroblasts, resulting in the generation of a broad range of "inflammatory" mediators including cytokines (i.e., IL-1β and TNF-α), MMPs, and ROS. Thus, a focal "oxidative stress" occurring in cartilage may initiate a vicious circle, constituted by ROS and further inflammatory mediators, leading to chronic synovium inflammation.

### 2.3 Endochondral Ossification

During vertebrate development, cartilage forms a model for many of the bones of the skeleton. This cartilage is replaced by bone (a process termed endochondral ossification) with accompanying long-bone growth until puberty is reached. Several studies have shown that endochondral ossification is reinitiated during osteoarthritis, leading to thickening of the calcified layer, doubling of the tidemark, and, consequently, thinning of the overlying cartilage. Some mechanisms have been advanced to explain endochondral ossification reactivation in OA cartilage. Some authors have suggested that cartilage neovascularization is associated with cartilage mineralization [55, 56], and that the loss the ability of cartilage to remain avascular could trigger endochondral ossification [57]. Although vascular endothelium growth factor (VEGF) expression in cartilage vanishes in normal adults, VEGF is known to be expressed in chondrocytes of OA cartilage [58, 59]. In parallel, the expression of chondromodulin-1, a cartilage-derived antiangiogenic factor, is reduced in OA cartilage [60], leading to an imbalance between pro- and anti-angiogenic factors. The excess of proangiogenic factors promotes vessel in-growth through the microcracks and calcified cartilage vascularization [61]. Another group of researchers have implicated inflammatory cytokines [21], including IL-1β and chemokines (IL-8/CXCL8) in endochondral ossification, suggesting a new mechanistic linkage between joint inflammation and dysregulated chondrocyte differentiation within OA cartilage. In vitro, these cytolines stimulate chondrocyte hypertrophic differentiation [21]. Recently, Cecil et al. [60] have proposed an additional mechanism to explain inflammation-induced chondrocyte hypertrophy. This mechanism involveds the upregulation of RAGE (receptor for advanced glycation end products) and ligand expression (including S100/calgranulins) by human chondrocytes in response to chemokines.

### 2.4 Synovium Inflammation

During OA pathology, the synovial membrane undergoes a moderate inflammation, which is commonly opposite the cartilage lesion, indicating a link between cartilage lesion and synovium inflammation. The inflammatory reaction is triggered by mediators released from cartilage lesion, including inflammatory cytokines, matrix peptides, and microcrystals. In response to these stimuli, synovial cells, including macrophages, T cells, and fibroblasts, produce high levels of inflammatory cytokines, ROS, and MMPs, which, in turn, directly degrade cartilage or stimulate chondrocytes to secrete more MMPs and ROS [62–65], resulting in an amplifying cycle and probably explaining the more rapid progression of chondropathy associated with a flare-up episode [66]. The link between synovitis and chondrolysis has been evidenced by a number of studies. A one year longitudinal study has demonstrated that a larger volume of effusion aspirations for painful OA knee predicted OA progression as defined by an increased narrowing of the joint space [67]. Arthroscopic studies have reported that a baseline synovitis score predicts subsequent worsening of chondropathy in post-traumatic patellofemoral damage [68] and in a large cohort of patients with knee OA [69]. Magnetic resonance imaging and ultrasonography have identified synovitis in early OA, even in the absence of clinical signs of synoviotis, indicating that synovitis is not a feature occurring only in severe and late OA [70]. Immunohistochemical studies have confirmed that synovial tissue from patients with early OA is characterized by mononuclear cell infiltration and the production of pro-inflammatory cytokines and mediators of joint damage, including ROS and MMPs. More recently, it was reported that the presence of inflammatory signs observed at ultrasonography was statistically associated with advanced radiographic disease as expressed by high radiological scores (Kellgren and Lawrence grades 3–4), and at an earlier stage (Kellgren and Lawrence grades 1–2) with clinical signs or symptoms suggestive of inflammatory flare-up [71]. Recently, Sturmer et al. [72] have found an association between pain intensity as measured by a visual analog scale and the serum level of the *C*-reactive protein (CRP) in patients with advanced OA.

### 2.5 Subchondral Bone Sclerosis

One of the mechanisms of initiation and/or progression of OA may be a steep stiffness gradient in the underlying subchondral bone, as the integrity of the overlying cartilage depends on the mechanical properties of its bony bed. Evidence from a primate animal model (*Macaca fascicularis*) of OA indicated that alterations of the bony bed may precede the changes in cartilage [73, 74]. Evidence for and against this hypothesis has recently emerged from both animal models studies [75] and clinical trials [76–78]. As articular cartilage slowly erodes, sclerosis of the subchondral bone also pro-

gresses, and subchondral bone stiffness increases in this tissue, possibly contributing to further mechanical disturbances of the cartilage. Trabecular thickening is characterized by an increase of osteoid substance deposition and by its abnormally low mineralization pattern. Further, it is now well established that OA osteoblasts show an altered phenotype and secrete more alkaline phosphatase (ALP), osteoclacine, interleukin (IL)-1, -6, TGF-β, IGF-1, and urokinase plasminogen activator (uPA) than normal osteoblasts. In contrast, they produce less parathyroid-related peptide (PTHrp) and parathormone receptor [79–81]. Based on their production of leukotriene (LT) $B_4$, prosteglandin (PG) $E_2$, and IL-6, two populations of osteoblasts have been identified. The first group produces high levels of $PGE_2$ and IL-6 but a low level of $LTB_4$, while the second group shows a production of $PGE_2$ and IL-6 similar to that of normal osteoblasts but a high production of $LTB_4$ [82]. These local metabolic changes are favorable to osteoid deposition and sclerosis formation. Furthermore, OA osteoblasts are resistant to parathormone (PTH) stimulation, a situation that can also contribute to abnormal bone remodeling [83]. Beside these quantitative modifications, the OA osteoblast phenotype is characterized by the production of abnormalty high levels of homotremetric type I collagen, which shows a low affinity for calcium [84]. These findings suggest that abnormal osteoblasts play a critical role in subchondral bone sclerosis.

### 2.6 Microcracks and Neovascularization

Osteoblasts secrete a number of biochemical factors that are involved in the remodeling of bone tissue, and these could also contribute to the remodeling of the overlying cartilage in weight-bearing joints after seeping through microcracks in the osteochondral junction. Three elements support this hypothesis: (1) microcracks have been identified at the osteochondral junction, allowing an exchange between the two tissues [85, 86]; (2) bone cell products (HGF, Osteocalcin) are detected in the synovial fluid and in cartilage [87–89]; and (3) primary osteoblasts of OA patients significantly induced glycosaminoglycans release from normal cartilage in vitro [89].

Taking all these observations into consideration, our laboratory has proposed the following hypothesis: OA-altered subchondral osteoblasts may contribute to the degradation of overlying cartilage by seeping of biochemical factors through the microcracks. To verify this hypothesis, we have developed an original co-culture model in which subchondral osteoblasts in the monolayer are cultured together with OA chondrocytes in alginate beads. Thus, we have demonstrated that osteoblasts from the sclerotic (SC) zone of subchondral OA, but not nonsclerotic (N) osteoblasts, downregulated agrecan synthesis and upregulated MMP-3 and MMP-13 expression by chondrocytes [79]. These findings suggest that osteoblasts of the sclerotic subchondral bone produce a pattern of biochemical factors that promote cartilage degradation.

## 3 REQUIREMENT FOR REGISTRATION OF DRUGS IN OA

Both the European Agency for the Evaluation of Medicinal Products (EMEA) and the U.S. Food and Drug Administration (FDA) have issued a guidance document to assist sponsors who are developing drugs, devices, or biological products to treat human OA [90, 91].

The U.S. draft guidance document [91] was released in July 1999, whereas the European "Points to Consider" document was issued in July 1998. Since both of these are slightly outdated, the Group for the Respect of Ethics and Excellence in Science (GREES), a European nonprofit organization seeking to prepare draft documents to be submitted, as working documents, to European regulators, performed an extensive search of the literature and, after setting up experts as consultants, produced new suggestions for the evaluation of guidelines for registration of agents for therapy of structure modification in OA [92, 93].

The current EMEA document offers a classification of antiosteoarthritis therapies dividing medications as symptom-modifying drugs and structure-modifying drugs. Symptom-modifying drugs act on symptoms with no detectable effect on the structural changes of the disease. Registration of such drugs would require demonstration of a favorable effect on symptoms with no clinically significant adverse effects or structural changes of the disease.

Structure-modifying drugs are expected to have an effect on the progression of the pathological changes of OA. These drugs may or may not have independent effects on symptoms.

### 3.1 Symptom-Modifying Drugs

Pain attributable to the target joint is recommended as the primary endpoint for symptom-modifying drugs for OA. Functional disability is an important additional primary endpoint for symptom-modifying drugs. Studies should be powered to demonstrate a significant effect both on pain and on functional disability. Pain should be measured by self-assessment with validated methods. Use and at-rest pain should be assessed separately. A disease-specific and joint-specific instrument such as the

Western Ontario MacMaster University Osteoarthritis Index (WOMAC) or the Lequesne index is recommended to assess disability arising from OA of the hip or the knee.

### 3.2 Structure-Modifying Drugs

Epidemiological data support a relation between structural changes and a long-term clinical outcome. However, the nature and the magnitude of the structural changes that are likely to be clinically relevant in the long-term remain uncertain. Therefore, clinical endpoints such as necessity of joint replacement, a time frame for the need for surgery, and long term clinical evolution are preferable in the assessment of efficacy of such drugs. The radiographic measurement of joint space width or osteophytes was, in 1998, considered as a promising tool to assess the progression of OA, although, at that time, its validity was not fully demonstrated. The EMEA considered that by providing the applicant with data supporting this surrogacy, these changes could be considered as alternative primary endpoints. In any case, the clinical endpoint had to be assessed during the study. Emphasis was put on the reproducibility of X rays on successive visits, which was considered as a prerequisite for a reliable assessment of the progression of OA. The agency requires that the method defines the radio anatomic position of the joint, the beam alignment, and the anatomic landmarks for measurements.

Due to the differences in OA of the knee and OA of the hand, extrapolation of results obtained on the lower limbs to the hand or alternatively extrapolations of data obtained on the hands to lower limbs was considered highly questionable. Compounds having demonstrated efficacy either at the hip or at the knee level would be registered for "treatment of OA of the knee and the hip," whereas a compound having shown efficacy at the level of the hands would be registered for "treatment of OA of the hands". In order to obtain the indication "treatment of OA," a compound should, in the opinion of the EMEA, demonstrate efficacy at the level of the hands and at the level of the knee or the hip.

It was suggested that clinical trials aimed at evaluating the effect of drugs in OA of the hand should be better focused on assessing progression of the disease in proximal and distal interphalangeal joints than in the trapezo-metacarpal joint. The EMEA felt that, although OA of the hand was a potential target for assessing evolution of disease in trials, it is less important clinically than hip or knee disease. OA of the hip was considered as a common and disabling disease, as was OA of the knee. Outcome measures for both symptoms and structure were better validated for medial tibio-femoral disease than for lateral or patello-femoral disease. If the spine was used as a target joint, it was the responsibility of the applicant to demonstrate the validity of the endpoints chosen and their clinical relevance. The agency suggested that, to improve the homogeneity of the patient groups studied, inclusion criteria should limit the target joint to a single site. However, simultaneous assessment of other joints was always considered as possible and such results might generate supportive evidence for "general" efficacy.

To be enrolled in a study, patients should have both symptomatic and structural changes of OA in the target joint. This means pain related to use with radiological evidence of joint space narrowing for OA of the hip and knee and the diagnostic criteria of the *American College of Rheumatology* for hand OA.

For studies of structure-modifying drugs, the inclusion in phase II studies of special subpopulations of subjects who are at high risk for development of OA or rapidly progressive OA may be advantageous (e.g., obese women with unilateral radiographical OA). However, inclusions of a specific risk group in phase III studies might decrease the potential for generalization of the results.

Pivotal study design and duration may differ according to the properties of the drugs.

***1. Modification of Symptoms*** Studies were requested to have a randomized, double-blind, parallel group design. Primary endpoints for efficacy should be evaluated after at least 6 months. To establish that the symptom-modifying drug does not have deleterious effects on the joint, structural changes should be monitored for at least one year. Controlled studies are necessary with the most favorable comparator. Three-arm, placebo, and active controlled studies are recommended by the EMEA.

***2. Modification of Structure*** Studies should have also a randomized, double-blind, parallel group design. Clinical variables or alternatively structural changes when their surrogacy value is proven are required as primary endpoints. When structural changes are chosen as primary endpoint, the magnitude of a clinically relevant effect of a drug on such variables over a specified time should be predetermined, based on previously established findings. Due to the expected mechanism of action of these drugs, long-term studies, no shorter than 2 years, were required both for efficacy and safety assessment. Studies should have a placebo-controlled, parallel group design.

When the FDA issued its draft guidance document in July 1999, the U.S. agency discussed a number of potential claims, including an *improvement in symptoms* claim and a *delay in structural progression* claim. The

guidance also proposes in principle, a *prevention of OA* claim.

The draft guidance document suggested to simultaneously assess pain and function and, as in the EMEA document, recommended the use of the Lequesne index and the WOMAC OA index. This document considered that patient global assessments (visual analogue scale or the likert scale) were overall measurements of whatever the patient feels is most important. They were considered as simple, unidimensional measurements that permit individualization of content and have been extensively validated in OA. The question as to whether patient global measurements should have a primary endpoint status similar to pain and function measurements remained open.

As with the EMEA, the FDA stated that structure was a critical component of OA assessment but that the relationships between structure and/or function and between structure and future outcomes were not well developed. The agency suggested that because OA is a disease of all the tissues in the joint, not just the cartilage, measurement of structure had to be seen broadly and capture important anatomic features, such as osteophytes or ligamentous instability, in addition to cartilage loss. However, since most likely, improvement in joint space narrowing implies cartilage preservation and would thus be reflected in clinical benefit, measurement of the joint space narrowing using an X ray was considered as an appropriate structure measurement. FDA requests that determination of what change in joint space narrowing of the knee or hip is clinically relevant to the patient should be established.

For symptom-modifying drugs, whereas efficacy endpoints include a measurement of pain, a global patient assessment and a self-administered questionnaire, a measurement of structure if the trial lasts a year or more is essential for risk–benefit assessment, even if no structure claim is sought. Trial duration for demonstration of symptom improvement should be at least 3 months.

For structural management, symptom endpoints should be collected regardless of the outcome anticipated. Trials to demonstrate structure improvement should last at least one year. The agency estimates that the claim of slowing joint space narrowing might plausibly be dissociated from other claims when the mechanism of action of the product and/or the size of the effect on slowing of joint space narrowing are suggestive of future clinical benefits. However, in general, the draft guidelines state that products will not be considered for approval for separate claims if (1) they are not anticipated to have different effects on these parameters or (2) they show only small improvements in joint space narrowing without demonstrated effects of symptoms.

The FDA offers a hierarchy of claims for structural outcomes, for example, *normalize the X ray, improve the X ray, and slow joint space narrowing by at least a prespecified amount*.

The draft guidance document introduces the claim *prevention of the occurrence of OA*, using symptomatic and radiographic criteria in patients with OA or in individuals at risk to develop OA in the future. However, the document states that the practicality of this outcome is challenged and that any trial used to demonstrate this outcome should first define the term *new OA*.

Since these two official regulatory documents are somewhat dated, European experts felt it appropriate to make a critical analysis of the available science and to provide European regulatory authorities with a working document that would update, if needed, the guidelines for registration of drugs for OA [92, 93]. The first objective of this working growp was to assess whether new technologies may be used for the assessment of disease-modifying drugs for OA.

Magnetic resonance imaging (MRI) is now used to measure parameters of cartilage morphology and integrity in OA patients. While some data are encouraging, correlation between short-term changes in cartilage structure observed with MRI and long-term radiographic or clinical changes are needed. Hence, the GREES suggests that $MRI_5$ be used as an outcome in phase II studies, but that further data is needed before accepting MRI as a primary endpoint in phase III clinical trials. Biochemical markers of bone and cartilage remodeling are being tested to predict OA and measure disease progression. Recently published data are promising but validation as surrogate endpoints for OA disease progression requires additional study. The GREES suggests that biochemical markers remain limited to "proof of concept" studies or as secondary endpoints in phase II and III clinical trials. However, the GREES emphasizes the importance of acquiring additional information on biochemical markers in order to help better understand the mode of action of drugs to be used in OA.

Regulatory agencies consider that evidence of improvement in clinical outcomes is critical for approval of structure-modifying drugs. Time to total joint replacement surgery is probably the most relevant clinical endpoint for the evaluation of efficacy of a structure-modifying drug. However, at this time, time to surgery cannot be used in clinical trials because of bias by non-disease-related factors such as patient willingness for surgery or economic factors. At this stage, it appears that structure-modifying drugs should demonstrate a significant difference compared to placebo. Benefit should be measured by three primary endpoints: joint space narrowing, pain, and function. Secondary endpoints should

include the percentage of patients who are "responder" (or "failure") patients. The definition of a "failure" patient would be someone with progression of joint space narrowing >0.5 mm over a period of 2–3 years or who has a significant worsening in pain and/or function, based on validated cut-off values. The definition clinically relevant cut-off points for pain and function must be based on data evaluating the natural history of the disease (epidemiological cohorts or placebo groups from long-term studies). These cut-off points should reflect a high propensity, for an individual patient, to later require joint replacement.

This working group organized then a second working group to assess the value of time to joint surgery as a potential therapeutic failure outcome criterion for OA of the hip or knee in the assessment of potential structure-modifying agents.

There are no accepted guidelines for "time to" and "indications for" joint replacement surgery. A limited number of trials have examined joint replacement surgery within the study population. Several parameters, particularly joint space narrowing (interbone distance), correlate with surgical intervention. However, at the level of the knee, none of the parameters have positive predictive value for joint replacement surgery better than 30%. In contrast, lack of significant joint space narrowing has a strong negative predictive value for joint replacement surgery (>90%), which remains after controlling for OA pain severity. At that time, GREES could not recommend time to joint surgery as a primary endpoint of failure for structure-modifying trials of hip or knee OA as the parameter has sensitivity but lacks specificity. In contrast, in existing trials, a lack of progression of joint space narrowing has predictive value of >90% for not having surgery. GREES suggests utilizing joint space narrowing (e.g., >0.3–0.7 mm) combined with a lack of clinically relevant improvement in symptoms (e.g., ≥20–25%) for "failure" as a secondary outcome in structure-modifying trials of the hip and knee.

## 4 WHAT'S A NUTRACEUTICALS?

Nutraceuticals are natural, bioactive chemical compounds that have health-promoting, disease-preventing, or medicinal properties (Table 2). They can be provided as dietary supplements delivered over the counter, as prescribed drugs (in a limited number of countries), or as functional food (see also [94]). As functional food, nutraceuticals are incorporated into food and drink products consumed as part of daily diet. A functional food can be defined as any food or food ingredient that may provide a health benefit beyond the traditional nutrients it contains [the Institute of Medecine's Food and Nutrition Board (IOM/FNB, 1994]. A functional food can be distinguished from a traditional food "if it is satisfactorily demonstrated to affect beneficially one or more target functions in the body, beyond adequate nutritional effects in a way which is relevant to either the state of well-being and health or the reduction of the risk of a disease" [95, p. 56]. A food product can be made functional by eliminating a deleterious ingredient, by adding a beneficial ingredient, by increasing the concentration of an ingredient known to have beneficial effects, or by increasing the bioavaibility or stability of a beneficial ingredient [96, 97].

**TABLE 2 Nutraceuticals in OA**

| | |
|---|---|
| Ascorbic acid | Hyaluronic acid |
| Avocado/soybean unsaponifiables | Hydrolysate collagen |
| *Boswellia serrata* | Methylsulfonylmethane |
| Bromelain | Milk and "hyperimmune milk" |
| Cat's claw | n-3 PUFAs |
| Chondroitin sulfate | *Ribes nigrum* |
| Cetyl myristoleic oil | *Rosa canina* |
| Collagen hydrolysate | Selenium |
| Glucosamine $SO_4$/Acetyl/HCL | Strontium |
| Chitosan | Silicium |
| Devil's claw | Turmeric |
| Flavonoids | Vitamin D |
| Green lipid mussel | Vitamin E |
| Ginger | Willow |

## 5 GLUCOSAMINE SULFATE (GS) AND CHONDROITIN SULFATE (CS)

CS and GS are aminosaccharides that act as preferred substrates for the biosynthesis of glycosaminoglycan chains and subsequently for the production of aggrecan. Glucosamine may be administrated as a prescription drug or as a dietary supplement over the counter. In fact, the patented crystalline GS 1500-mg once-a-day soluble powder preparation used in the most relevant clinical trials is a prescription drug in most European and some non-European countries, whereas the Dietary Supplement Health and Education Act of 1994 favored the appearance on the dietary supplement market in the United States and other countries of several poorly documented glucosamine salts (e.g., hydrochloride), derivatives (e.g., N-acetyl-glucosamine), or dosage forms and regimens.

Recently, the oral bioavailability and pharmacokinetic ability of the patented crystalline GS has been determined in humans, with a newly developed and

validated liquid chromatography method with mass spectrometry detection (LC-MS/MS), having a low limit of quantitation (LOQ = 6.25 ng/mL = 0.03 μ*M*) [98]. Endogenous plasma levels of glucosamine were detected (10.4–204 ng/mL). After oral administration of the standard therapeutic once-daily dosage of 1500 mg crystalline GS, glucosamine plasma levels increased over 30-fold from baseline and peak at about 10 μ*M* (9.92 μ*M* or 1777.6 ng/mL) after 3–4 h, indicating that the drug is orally bioavailable at concentrations that are in line with those found to be effective in in vitro models. After 14-day consecutive once-daily administrations of 1500 mg GS, glucosamine maximum plasma concentrations in healthy subjects (8.9 ± 0.7 μ*M* or 1602 ± 123 ng/mL) are similar to those reached at corresponding sampling times in both plasma (7.9 ± 1.9 μ*M* or 1419 ± 312 ng/mL) and synovial fluid (7.2 ± 1.4 μ*M* or 1291 ± 257 ng/mL) of knee OA patients [99]. The compound was eliminated with $t_{1/2}$ estimated to be 15 h, supporting once-daily dosing. Conversely, other glucosamine formulation (i.e., glucosamine hydrochloride 500 mg three times a day) provide peak plasma levels in OA patients that are below 3 μ*M* [98, 99].

As common in mechanistic studies, most of the in vitro studies performed so far to characterize GS mechanism of action have used higher concentrations than those found after therapeutic doses in biological fluids in humans (that were previously unknown). In vitro, CS (100–1000 μg/mL) and GS (50–100 μg/mL) increased the production of proteoglycans by chondrocytes, with no detectable effects on collagens, or cell proliferation [100]. They also partially counteracted the effect of IL-1β on proteoglycan and MMP synthesis, suggesting that these compounds may interfere with the deleterious effects of one of the most active mediators of OA pathology [101–103]. Both CS and GS inhibit IL-1-induced COX-2 and $PGE_2$ synthesis, with no effect on the constitutively expressed COX-1, indicating that these compounds may have anti-inflammatory properties. GS may also have cyclo-oxygenase-independent anti-inflammatory properties, by inhibiting nuclear factor-κB (NF-κB) binding activity, and subsequently decreasing anti-inflammatory cytokines (i.e., IL-6, IL-1β, TNFα), metalloproteases (MMP-3 and ADAMTS5), and ROS production ($^{\bullet}NO$) [104, 105]. Effects connected with NF-κB decreased activation are already evident at concentrations of 10 μ*M*. Finally, a strong ROS scavenging effect was also observed in PMA-activated leukocytes by GS ($IC_{50}$ 0.16 ± 0.02 m*M*) [106]. At this time, the role played by sulfate in the biological activities of these compounds remains controversial. Sulfate-containing chondroprotective agents selectively increase serum concentrations of inorganic sulfate, suggesting that sulfate may mediate the therapeutic effect of GS or other sulfur-containing agents [107, 108]. However, until now, there is only one in vitro study comparing in similar cultural conditions the effects of acetylated glucosamine, sulfated glucosamine, and galactosamine. This study demonstrated that GS, but not acetyl glucosamine or galactosamine, inhibited in a dose-dependent manner (10–1000 μg/mL) the synthesis of pro-inflammatory mediators by IL-1β-stimulated human osteoarthritic chondrocytes through an NF-κB dependent mechanism [104]. This study underlined the role played by sulfate substitution in the biological activity of aminosaccharides. In contrast, Neil et al. [109] have reported that glucosamine-HCL at concentration of 10 μg/mL significantly reduced IL-1β-induced messenger ribonucleic acid (mRNA) expression of MMP-13, aggrecanase-1, COX-2, iNOS, and c-Jun-N-terminal kinase (JNK), while CS had no effect on gene expression at the concentrations tested. In the same way, glucosamine-HCL also reduces $NO_2^-$ and $PGE_2$ production induced by IL-1β and is able to fully prevent the upregulation of stromelysin (MMP-3) mRNA expression by IL-1β. Furthermore, the addition of glucosamine to rat chondrocytes treated with IL-1β decreased the activation of NF-κB, but not activator protein-1 and increased the expression of mRNA-encoding type IL-1β receptor [110]. Finally, Chan et al. [111] reported that a physiologically relevant concentration (1–20 μg/mL) of glucosamine-HCL downregulated IL-1β-induced gene expression of inducible nitric oxide synthase (iNOS) and cyclo-oxygenase-2 (COX-2) and repressed the cytokine-stimulated microsomal prostaglandin E synthase-1 (mPGEs1) transcript leading to the reduced synthesis of $^{\bullet}NO$ and $PGE_2$ in cartilage [112]. These data suggest that sulfate is probably not the only active group involved in the effects of GS in a medium supplemented in sulfur amino acids.

Crystalline GS was found to be effective in controlling OA symptoms in several clinical trials [113–115]. In particular, two randomized, placebo-controlled, double-blind trials of 3-year duration in knee OA patients showed that this symptom-modifying effect is sustained over long-term courses [116, 117]. Recently, two multicenter, randomized, placebo-controlled, double-blind clinical studies have been assessing the efficacy of oral glucosamine over a medium-term—6 months—treatment course in knee OA, using a standard symptomatic medication as a reference. These studies were named the Glucosamine/Chondroitin Arthritis Intervention Trial (GAIT) [118] and Glucosamine Unum in Die Efficacy (GUIDE) studies [119]. GAIT was performed by the National Institutes of Health (NIH) in the United States with nutraceutical glucosamine-HCL 500 mg t.i.d., while GUIDE has been running in Europe with the prescription GS formulation

1500 mg once a day. In the GAIT study, 1587 patients with symptomatic knee OA were randomly assigned to receive 500 mg glucosamine-HCL three times daily, 400 mg of sodium chondroitin sulfate three times daily, 500 mg of glucosamine-HCL plus 400 mg of chondroitin sulfate three times daily, 200 mg of celecoxib daily, or a placebo. The primary outcome measure was a response treatment, defined a priori by expert consensus as 20% decrease in the summed score for the WOMAC pain subscale from baseline to week 24. Analysis of the primary outcome measure revealed that the rate of response to glucosamine-HCL and chondroitin sulfate, either alone or in combination, was not significantly higher than the rate of response to placebo, while the rate of response to the celecoxib control was significantly higher than that for the placebo control. Nevertheless, the treatment effects in the moderate-to-severe pain stratum (WOMAC pain score, 301–400) were more substantial. Results for the primary outcome in this stratum, which included 22% of the patients in the trial, indicated that combined treatment was significantly more effective than placebo. Nevertheless, these results must be interpreted with caution and in regard to the following limitation. First, the high rate of response to placebo (60.1%) and the relatively mild degree of pain from OA among the participants may have limited the ability to detect benefits of the treatment. Second, It is confirmed that glucosamine-HCL is, at best, only partially effective, probably because of the absence of sulfates and, especially, because of the low glucosamine peaks achieved with the T.I.D. administration.

In the GUIDE study, 318 subjects with knee OA were randomly assigned to receive 1000 mg acetaminophen three times a day (total 3 g acetaminophen/day, i.e., the approved daily dose in Europe), 1500 mg crystalline GS once a day, or the appropriated placebo. The Lequesne index (change in score at 6 months) was designated as the primary efficacy outcome in the protocol, since it was used to calculate the study sample size. GS, but not acetaminophen, significantly reduced the Lequesne score, indicating that crystalline GS at the oral once-daily dose of 1500 mg should be the preferred symptomatic medication for medium- and long-term treatment in patients with knee OA.

## 6 HYALURONIC ACID

Several hyaluronic acid (HA) preparations are currently available in the United State, Canada, and Europe and are used to treat knee, hip, carpometacarpal joint of the thumb, or ankle OA (Table 3). These preparations require three (Synvisc, high-molecular-weight cross-linked HA, Orthovisc) to five (Hyalgan, Supartz) intra-articular (IA) injections (1–2 mL containing 10–20 mg/mL HA per injection depending on the joint). Significant adverse effects are limited to rare acute local reactions, such as transient pain or warm joint lasting for one night. Recently, four systematic review and meta-analysis [3, 120–122] including randomized controlled trials published until 2004 have reached different conclusion about the effectiveness of HA on knee OA symptoms. Arrich et al. [121] concluded that HA has not been proven clinically and may be associated with a greater risk of adverse events. Lo et al. [120] concluded that at best there is a small effect compared to placebo injection. Maheu and collaborators [122] have reviewed 24 clinical trials on hyalgan. They concluded that 3–5 weekly injections of Hyalgan significantly improved the pain and functional status of patients with OA and that, although the onset of improvement was delayed by 3–4 weeks, the effect can last at least 6 months and more after treatment cessation. Finally, the fourth systematic review [3], which is an update of the recommendations of the European League Against Rheumatism (EULAR) for the management of knee OA, concluded that there is evidence to support the efficacy of HA in the management of knee OA both for pain reduction and functional improvement.

**TABLE 3 Hyaluronic Acid Preparations**

| Trade Name | Corporation | Average MW (kDa) |
|---|---|---|
| Synvisc (Hylan G-20) | Biomatrix (Canada) | 6000–7000 |
| Healon | Pharmacia/Upjohn (Sweden) | 1900–3900 |
| Orthovisc | Anika (USA) | 1700–2900 |
| Arthrum | LCA (France) | 2000 |
| Adant | Meiji Seika (Japan) | 900–1200 |
| SupArtz, Artz, Artzal | Seikagaku (Japan) | 600–1200 |
| Ostenil | Chemedica (France) | 1200 |
| Hyalgan | Fidia (Italy) | 500–730 |

At least, 10 additional clinical trials have been published since 2004 [123–131]. A large majority of these clinical trials reported beneficial effects of HA on OA symptoms, not only for knee OA but also for ankle or carpometacarpal joint of the thumb OA [123–128, 131–133]. Recently, Fuchs et al. [126] reported that a single course of three injections of sodium hyaluronate (Ostenil mini) was effective in relieving pain and improving joint function in patients with OA of the carpometacarpal joint of the thumbs. Although in comparison with triamcinolone its effects are achieved more slowly, the results indicate a superior long-lasting effect

of hyaluronan at 6 months after end of treatment period. The effects of intra-articular hyaluronic acid (Artz) have been investigated in a prospective study including 93 patients with ankle OA. The authors concluded that five weekly IA injections of Artz provided pain relief and functional improvement in patients with radiological Kellgren-Lawrence grades I and II ankle OA. The clinical effect was rapid at 1 week and may last for 6 months or more [131]. Similarly, Hyalgan provided sustained relief of pain and improved function in patients with ankle OA compared to placebo [133]. Two recent studies [127, 128] have compared the efficacy of hylan G-F 20 (Synvics) and sodium hyaluronan (Orthovics) in the treatment of knee OA. With a molecular weight of 6000 kDa, the elastoviscous properties of hylan G-F20 (Synvics) are similar to those of the synovial fluid of healthy young adults [134]. The viscoelastic properties of hyaluronan (Orthovics) is lower than that of the hyaluronan in normal healthy synovial fluid, with a molecular weight of 1550 kDa. Both hyaluronan preparations induced a marked reduction of pain and improved function of patients with knee OA, but there was no significant difference between the two preparations.

Aside from the symptomatic efficacy of intra-articularly injected HA in OA, growing preclinical and clinical evidence indicates that HA may modify the progression of OA. In animal OA induced experimentally by menisectomy or anterior cruciate ligament transection, Artz, Hyalgan and Synvisc have been shown to reduce OA lesion progression (evaluated macroscopically or histologically) compared to saline injection (see details in [135]). In humans, clinical evidence is limited to short-term studies (≤1 year) evaluating disease-modifying effects of Hyalgan. The majority of these studies used arthroscopy or morphology as the outcome parameter [136–138]. Until now, only one large multicenter, double-blind, randomized study involving 408 patients with OA of the knee was carried out using joint space narrowing over 1 year as primary outcome measure [139]. In this study, patients received 3 courses of 3 weekly injections of Hyalgan or placebo (saline every 4 months). In comparison with placebo, Hyalgan significantly reduced the progression of joint space narrowing in the subset of patients who had higher joint space area at study entry (>4.6 mm). In contrast, there was no statistical difference between treatment groups when comparing the change in joint space width (JSW) in the patients with more severe OA at entry (<4.6 mm). It appears that HA acts on cartilage through various mechanisms of action, including the inhibition of catabolic cytokine (IL-1β, TNF-α) activities and synthesis [140, 141], the reduction of ROS production [142], and the stimulation of matrix synthesis [141, 143]. These effects are conducted by binding cluster of differentiation 44 (CD44) receptors [144, 145] and intracellular HA binding proteins (receptors) called receptors for hyaluronan-mediated mobility (RHAMMs) (see details in [146]).

Based on this global overview of the HA clinical trials, HA is particularly indicated—In painful OA despite other pharmacological and nonpharmacological therapies, radiologically moderate, with no or mild effusion, in the absence of mechanical symptoms—as the second-line treatment after a period of acute radiological chondrolysis when knee "dryness" has been obtained—in painful "endstage" OA when total joint replacement is contraindicated or refused by the patient and—as an alternative to NSAIDs when contraindicated, not tolerated, or inefficient.

## 7 LIPIDS

### 7.1 Avocado–Soybean Unsaponifiables

Avocado–soybean unsaponifiables, or ASUs are derived entirely from vegetable sources. ASU have been used in France as prescription treatment for OA, subsidized by the government, and meticulously tracked for safety for over 15 years. Piascledine300 (Laboratoires Expansciences, Courbevoie, France) is the name of the French prescription form of ASU. A Piascledine300 pill is composed by 100 mg of avocado oil and 200 mg of soybean oil. In other countries, ASU mixtures are available as a supplement and their compositions are different to that of Piascledine300. Indeed, ASU contained in Piascledine300 result from a specific extraction procedure that confers chemical particularities to this drug. Therefore, the extrapolation of the therapeutic effects of Piascledine300 to over-the-counter preparations is hazardous. Finally, eating avocado and soy, even in large amounts, does not provide enough of the unsaponifiable to have a therapeutic effect. In fact, less than one percent of the avocado and soy oils make up the unsaponifiable fraction of these oils.

In vitro, Piascledine300 displayed anabolic, anticatabolic, and anti-inflammatory effects on chondrocytes. Piascledine300 increased collagen synthesis [147] and inhibited the spontaneous and IL-1β-induced collagenase activity [148, 149]. This drug increased the basal synthesis of aggrecan and reversed the IL-1β-induced reduction of aggrecan synthesis [150]. It reduced the spontaneous and IL-1β-induced production of MMP-3, IL-6, IL-8, and $PGE_2$ while weakly reversing the IL-1β-induced decrease in tissue inhibitor of metalloproteinases-1 (TIMP-1) production [148–150]. It decreased the spontaneous production of ˙NO and macrophage inflammatory protein-1β (MIP-1β) [27] but

stimulated the expression of TGF-β1 and plasminogen activator inhibitor-1 [151]. Recently, it was reported that Piascledine300 inhibited P42/44 mitogen-activated protein kinases (MAPK) activity and NF-κB binding activity induced by IL-1β or a mechanical stress, suggesting a new mechanism of action for this drug [152]. Furthermore, we have demonstrated that Piascledine300 fully prevented the inhibitory effect of OA osteoblasts on cartilage matrix protein production by human OA chondrocytes [153]. This finding suggests that Piascledine300 could act on subchondral bone and thus have a beneficial effect on the overlying cartilage. Furthermore, this finding contributes to explaining the effect of Piascledine300 on subchondral bone sclerosis observed in sheep with lateral menisectomy [154]. In this animal model, Piascledine300 (900 mg/5 days per week) for 6 months reduced the toluidine blue stain in cartilage and prevented subchondral bone sclerosis in the inner zone of the lateral tibial plateau but not focal cartilage lesion.

Four double-blind placebo-controlled randomized controlled triads (RCTs) and one systematic review evaluated Piascledine300 on hip and knee OA [155–158]. In two 3-month RCTs, one on knee and hip OA [156] and one solely on knee OA [155], 300 mg of Piascledine300 once a day decreased NSAID intake. No statistical difference in any primary or secondary endpoints was detected between 300 and 600 mg once a day [155]. In a 6-month RCT on knee and hip OA, 300 mg once a day resulted in an improved lequesne functional index compared to placebo [157]. Only one study has evaluated the structure-modifying effect of Piascledine300 on OA. In this 2-year RCT on hip OA, Piascledine300 once a day did not slow down joint space width narrowing [158]. In addition, none of the secondary endpoints (Lequesne functional index, VAS pain, NSAID intake, and patients' and investigators' global assessments) were statistically different from placebo after one year. A post hoc analysis suggested that ASU might decrease joint space width narrowing in patients with severe OA (JSW ≤ median at baseline). In summary, while Piascledine300 might display medium-term (several months) symptom-modifying effects on knee and hip OA, their symptom-modifying effects at long term (over a year) have not been confirmed. Furthermore, the structure-modifying effect of ASU needs to be further investigated. Finally, its safety record is good with no significant differences in adverse effects between Piascledine300 and placebo.

### 7.2 Omega-3 Polyunsaturated Fatty Acids (n-3 PUFAs)

PUFAs are classified into n-3, n-6, and n-9 depending on the position of the last double bond along the fatty acid chain. The main dietary PUFAs are n-3 (such as linoleic acid and eicopentenoic acid) found in vegetable oils (soybean and canola oils), flaxseeds, walnuts, or fish oils, and n-6 (such as linoleic acid and arachidonic acid) found in vegetable oils (corn, soybean, sunflower) and in meat. Modern western diet is relatively low in n-3 PUFAs and relatively high in n-6 compared with eastern diets or diets in preindustrialized societies. A high n-3 intake correlates with low incidence of cardiovascular and inflammatory diseases [159, 160].

The articular cartilage content of arachidonic acid, an n-6 precursor of pro-inflammatory prostaglandins $PGE_2$, correlates with severe OA [161]. Dietary lipid interventions in animals modified the PUFA composition of articular cartilage [162]. The in vitro effects of 10–100 μg/mL of n-3 fatty acid (linoleic, eicopentaenoic, and docosahexaenoic acids) on chondrocytes have been investigated [163, 164]. The n-3 fatty acid did not affect the spontaneous GAG synthesis or its IL-1-induced decrease, but dose-dependently inhibited the IL-1-induced GAG release. They dose-dependently inhibited the IL-1-induced aggrecanase activity and basal and collagenase activity, whereas, in contrast, n-6 stimulated the basal aggrecanase and collagenase activity. They also decreased the IL-1-induced mRNA expression of ADAMTS-4 (aggrecanase), COX-3, 5-LOX, FLAP (5-LOX-activating protein), IL-1α and TNF-α, and the basal mRNA levels of these genes [165]. Finally, they decreased the basal and IL-1β-induced mRNA and protein levels of MMP-3 and -13. All these parameters were unaffected by n-6 PUFAs [163, 164]. Taken together, these results indicate that n-3 PUFAs have anti-inflammatory and anticatabolic properties. Nevertheless, a too low n-6 : n-3 ratio can be detrimental. A diet with very low levels of n-6 PUFAs induced occasional surface irregularities and localized proteoglycan depletion in cartilage in rats [162].

### 7.3 Lipid Extract from New Zealand Green-Lipped Mussel (Perna canaliculus)

The reason people first marketed p. *canaliculus* stems from the observation that native New Zealanders (Maoris) who lived near the sea had a much lower incidence of arthritis than their relatives who lived inland. Their diets were similar with the exception that the Maoris on the coast consumed large amounts of the green-lipped mussel.

Green-lipped mussel *(P. canaliculus)* is a New Zealand shellfish from which an extract has been shown to be useful in the treatment of rheumatoid arthritis (RA) and OA. The patented and stabilized lipid extract, with the trademark name of Lyprinol, contains a variety of fatty acids, including eicosatetraenoic acid (ETA), which is an omega-3 fatty acid.

Lyprinol acts as a dual inhibitor of cyclo-oxygenase and lipoxygenase pathways, limiting the production of protaglandins and leukotrienes, two mediators of joint inflammation and pain [166]. Lyprinol (50 mg) is administrated orally in capsule form (~260 mg, 2–4 capsules per day according to the manufacturer recommendations) containing natural monosaturated olive oil (100 mg) and vitamin E (D-alpha-tocopherol—0.225 mg) as an antioxidant.

In a 6-week double-blind placebo-controlled RCT in dogs, 1 g per day of Lyprinol directly incorporated as 0.3% in a dry diet significantly improved total arthritic score, joint pain, and joint swelling [167]. More than 50% of the dogs demonstrated a 30% or greater reduction in total arthritic score. However, it is unclear whether these dogs suffered from OA specifically and the disease severity was not described.

In a multicenter 2-month clinical trial, 60 patients with symptomatic knee and hip OA, receiving Lyprinol at a dose of 2 capsules twice a day, showed a significant reduction of the Lequesne functional index, suggesting that Lyprinol might improve the algofunctional status of OA patients without adverse effects [168].

## 8 VITAMINS AND MINERALS

The effects of vitamins C, E, and B on OA have been formally investigated. One obvious candidate not yet evaluated is vitamin D (vit D). However, structural and metabolic changes in OA subchondral bone suggest that vit D could play a role in this process. In addition, cartilage mineralization is an important feature of severe OA, and the expression of vit D receptors is upregulated in human OA chondrocytes [30]. Hence, suboptimal levels of vit D may impair bone and cartilage metabolism and predispose one to OA. The Framingham study found a threefold increase in risk of OA progression for patients in the middle and lowest tertile of serum levels of 25 vitD [169]. Low serum levels of vit D also predicted loss of joint space and osteophyte growth. The women's study of osteoporotic fractures found that the risk of incident hip OA defined by joint space narrowing was increased for patients in the middle and lowest tertiles of serum levels of 25 vit$D_3$ [170]. Based on these data, an RCT testing the efficacy of vit D seems to be required.

### 8.1 Vitamin C

In vitro, vitamin C (vit C) increases protein and proteoglycan synthesis by articular chondrocytes [171–173] and increases the mRNA levels of type I and II collagens [171, 174], aggrecan, and aprolyl 4-hydroxylase [171]. It decreases the LPS-induced GAG release [175]. It also affects the activities of lysosomal enzymes decreasing the activities of arylsulfatase A and B, but increasing the activities of acid phosphatase in normal and OA chondrocytes [172].

Vit C can cross-link collagen and other proteins, by nonenzymatic glycation leading to the formation of advanced glycation end (AGE) products. Threose, a metabolite of ascorbic acid, increases the AGE content of articular cartilage in vitro [176]. These cross-links increase the stiffness of the collagen network, which is hypothesized to increase cartilage susceptibility to OA. High in vitro levels of vit C (756 m*M*) also increase protein carbonylation, one type of oxidative damage [171]. However, when guinea pigs were fed with diets containing different levels of vit C, no modification in the AGE content of articular cartilage was detected [177].

In guinea pigs, 8 months of exposure to a very high dose (150 mg per day) of vit C decreased the severity of surgically induced knee OA [178] but increased severity of spontaneous OA [177], despite the ability of ascorbic acid to increase cartilage collagen content. A third guinea pig trial stated, on the contrary, without providing any details, that a fivefold increase of ascorbic acid to the drinking water (equivalent of 1 g per liter) had a slight chondroprotective effect on the development of spontaneous lesions but not on surgically induced OA [179].

The Framingham epidemiological study found a threefold reduction in risk of OA progression for both the middle and highest tertile of vit C intake (an average of 152 and 430 mg per day, respectively) and an inverse association between vit C intake and cartilage loss [169]. No association between vit C intake and osteophyte growth or disease incidence was found. A protective effect was also demonstrated for vit E and β-carotene, but this effect was less evident and consistent than in the case of vit C. The favorable effect of vit C was probably related to the fact that vit C is not only an antioxidant but is also an important cofactor in type II collagen synthesis. In a 14-day double-blind cross-over RCT on knee and hip OA, 1 twice a day of calcium ascorbate was more efficient than placebo in decreasing pain VAS [180]. However, the measured effect was small (a 4.6-mm decrease from a starting basal level of 50 mm) and obtained with a dose equal to the upper tolerable intake level for adults, well above the current 60–200 mg per day recommended daily allowances (RDAs). The long-term safety of such high doses of vit C in elderly OA patients needs to be evaluated while efficacy needs to be confirmed by longer RCTs. In view of these conflicting results and in the absence of strong evidence of efficacy in humans, it was recommended that vit C intake for OA should not be higher than the currently RDAs (90 mg per day for men and 75 mg per day for women) [177].

### 8.2 Vitamin E

Natural vitamin E (vit E) comprises eight different forms, α-, β-, γ-, and δ-tocopherol and α-, β-, γ, and δ-tocotreinol, found solely in plants. One of the most important food sources of vit E is edible plant oils. Synthetic α-tocopherols (the eight other possible side-chain stereisomers besides the natural one) and their esters (α-tocopherylsuccinate, α-tocopherylacetate) also exist. α-Tocopherylacetate is often used commercially because vit E esterification protects it from oxidation. In the human body, the ester is rapidly cleaved by cellular esterases making natural vit E available.

Only a few studies have investigated the in vitro effects of vit E on chondrocytes. Tiku et al. [47] showed that when chondrocytes were submitted to an oxidative stress, vit E reduced the catabolism of collagen by preventing the protein oxidation mediated by aldehydic downproducts of lipid peroxidation. Vit E strongly increased the sulfate incorporation while slightly reducing glycoprotein and glycolipid synthesis. Like vit C, vit E affected the activities of lysosomial enzymes: It decreased the activities of arylsulfatase A and of acid phosphatase in cultures of human articular chondrocytes [181]. However, vit E did not affect the LPS-induced catabolism of GAGs and did not prevent synoviocyte apoptosis induced by superoxide anions [182].

Five RCTs have tested the natural form of vit E or α-tocopherylacetate. Two trials concluded that vit E was more efficient than placebo in decreasing pain. In a small 10-day single-blind cross-over RCT on mainly spondylosis, 600 mg of vit E per day was superior to placebo as assessed by a patient's questionnaire [183] while in a 6-week double-blind RCT on OA, 400 IU of α-tocopherylacetate once a day was superior to placebo as assessed by a joint patient/doctor, global assessment of pain [184]. One trial suggested that vit E was no less efficient than diclofenac in decreasing pain. In a 3-week double-blind RCT on OA, no significant difference was found between 544 mg of α-tocopherylacetate 3 times a day or 50 mg diclofenac 3 times a day on VAS of pain [185]. However, the two most recent trials failed to show any benefit over placebo on knee OA. In a 6-month double-blind RCT, 500 IU of vit E a day showed no symptomatic benefit over placebo as assessed by WOMAC [186], while in a 2-year double-blind RCT, 500 IU of vit E a day showed no symptomatic or structure-modifying benefit over placebo as assessed by WOMAC or MRI, respectively [187]. Although 3 out of the 5 RCTs concluded that vit E decreased pain, the two longest, largest, and highest quality trials failed to detect any symptomatic or structural effects in knee OA, indicating that, at least for knee OA, vit E has no medium-term beneficial effect. No significant adverse event was reported.

### 8.3 Vitamins B

Vitamin $B_6$ deprivation induced disorders in avian articular cartilage, including a decreased content and increased extractability of total sulfated PGs from articular cartilage with guanidine HCl. These findings suggest that vitamin $B_6$ could be a necessary diet compound to maintain cartilage homeostasis [188].

Until now, only one double-blind study has demonstrated the efficacy of niacinamide (vitamin $B_3$) in OA. In this 3-month double-blind RCT, very high doses of niacinamide (500 mg 6 times per day) were more efficient than placebo in reducing drug intake and OA symptoms at the exception of pain [189]. A 2-month double-blind cross-over RCT in hand OA comparing 6400 μg of folate with or without 20 μg of cobalamin (vitamin $B_{12}$) daily to placebo failed to show significant effects on mean hand grip values [190]. Nevertheless, among patients with low hand grip values, the acetaminophen consumption was fewer in the cobalamin/folate group than in the placebo group. Recently, it was reported that the chondroprotective effect of glucosamine-HCL/CS mixture was enhanced by the addition of fursultiamine, a vitamin $B_1$ derivative, in rabbit OA induced surgically by menisectomy [191]. This effect was associated with a reduction in the level of MMP-1, which is known to play an important role in the pathogenesis of OA lesions. In these studies, no severe adverse effects have been reported. Altogether, these findings suggest that vit B supplementation may be of value in the treatment of OA; however, even larger studies are needed to confirm the beneficial effect of vit B on the natural course of OA.

### 8.4 Cocktail of Vitamins and Selenium

Because vitamins are rarely consumed separately, it makes sense to study the effects of a cocktail of vitamins. Two cocktails of vitamins containing selenium and a cofactor of the anti-oxidative enzyme glutathione peroxidase have been investigated. In a small pilot 6-month double-blind placebo-controlled RCT, a mixture of vitamins A, C, and E (in undisclosed amount) and 144 mg of selenium per day had no effect on VAS of pain or stiffness [192]. Vitamins A, C, E, $B_2$, and $B_6$ and selenium decreased OA incidence and severity in STR/1N mice, possibly through an antioxidant effect as suggested by the increased expression of two antioxidative enzymes, glutathione peroxidase and superoxide dismutase in cartilage [193].

## 9 PHYTOCHEMICALS AND PLANT EXTRACTS

### 9.1 Bromelain

Bromelain is present in all parts of the pineapple plant (*Anana cosmosus* Merr, mainly var Cayenne from the family of Bromeliaceae), but the stem is the most common commercial source. Bromelain is marketed as a crude, aqueous extract that contains a mixture of sulfur-containing protein-digesting enzymes and several other substances in smaller quantities, including peroxidase, acid phosphatase, protease inhibitors, and calcium. Bromelain was suggested to have anti-inflammatory, analgesic, antiedematous, antithrombotic, and fibrinolytic effects (see [194, 195] for a review). Three different preparations containing bromelain mixed with varied enzymes have been tested in nine trials on knee OA (see [194, 196] for a review and references). Bromelain was taken in tablets coated to resist stomach digestion at a daily dose ranging from 270 to 1890 mg. All nine trials might have been insufficiently powered, were of short duration (3–6 weeks), and enrolled OA patients with flare-up episodes. Most used the Lequesne functional index as a primary endpoint. Bromelain was shown to be no less or even more effective than 100–150 mg of diclofenac per day in seven trials, it was also not more efficient than placebo in two other trials. This absence of efficacy over placebo, coupled with the fact that in some diclofenac-controlled trials the Lequesne functional index continued to decrease in both groups even 4 weeks after the end of treatment [197], suggested a possible spontaneous resolution of the flare-up episode rather than a real efficacy of bromelain [194]. Longer trials of higher quality were advocated to confirm the efficacy of bromelain [194]. In one trial, a high dose of bromelain (945 mg/day) induced a higher incidence of adverse effects and drop-outs compared to diclofenac (questioning its safety and tolerability) [198].

### 9.2 Rosa canina

A standardized rose-hip powder made from the seeds and husks of the fruits from a subtype of *R. canina* (Hyben Vital), the common wild briar rose of English hedgerows, was evaluated in three RCTs. This extract contains a large amount of flavonoids and vit C and possess powerful antioxidant properties [199]. In a 4-month double-blind RCT on hip and knee OA, 2500 mg of this powder twice a day did not improve active or passive mobility (joint rotation, flexion, and extension) compared to placebo, except passive hip flexion [200]. In a 3-month cross-over double-blind RCT, 2500 mg of *Rosa* powder twice a day decreased pain (as measured by a categorical scale) more efficiently than placebo when placebo was administrated first but not when it was administrated second [201]. No pain difference was found when the two groups were compared before cross-over. This RCT, which enrolled patients with OA in various joints, did not include a washout period. In a 3-month cross-over double-blind RCT on knee and hip OA, which included a 3-week washout period, 2500 mg *Rosa* powder twice a day was more efficient than placebo in decreasing WOMAC pain after 3 weeks of treatment but not after 3 months [202]. At 3 months, the *Rosa* treatment decreased the WOMAC function and stiffness subscales (secondary endpoints) more efficiently than placebo. No major side effects were reported in the three RCTs. Hence, further research on this extract is required before making any conclusion about its efficacy or lack of efficacy.

### 9.3 Harpagophytum procumbens (Devil's Claw)

*H. procumbens,* also called devil's claw, is a South African plant that grows in regions bordering the Kalahari. Secondary tuberous roots are used to prepare powders or extracts, which were tested in several RCTs (see [203, 204] for reviews). Product standardization is based on the content of harpagoside, the principal compound found in the raw material. In all RCTs, the harpagoside content was similar and above 50 mg/day.

Recent in vitro studies indicate that preparations from *H. procumbens* may interact with the inflammatory cascade, including the inhibition of cytokines, COX and ROS production, through the suppression of NF-κB activation [205, 206]. An extract of the secondary root of *H. procumbens* reduced the IL-1β-induced production of MMP-1, MMP-3, and MMP-9 proteins by human chondrocytes [207].

A systematic review of the efficacy of *Harpagophytum* for OA concluded that evidence of the effectiveness of *Harpagophytum* products is not transferable from product to product. There is limited evidence of the efficacy for ethanolic extract providing less than 30 mg of harpagoside, one of the major compounds of *H. procumbens,* per day in the treatment of knee or hip OA and moderate evidence of efficacy for the use of powder providing 60 mg of harpagoside daily in the treatment of spine, hip, and knee OA [208]. In a 2-month double-blind RCT on spine and knee OA, 670 mg of *Harpagophytum* powder 3 times a day were more efficient than placebo in reducing VAS of pain [209]. In a 4-month double-blind diacerhein-controlled RCT on hip and knee OA with flare-up episodes at inclusion, 2.6 g of *Harpagophytum* powder per day were no less efficient than 200 mg of diacerhein per day in improving VAS of pain [210, 211]. No safety concerns appeared

from the 4300 patients that received *Harpagophytum* products. In a uncontrolled observational study, 0.8 g of an aqueous extract 3 times a day reduced blood sedimentation time and C-reactive protein levels [212].

### 9.4 Uncaria tomentosa and Uncaria guianensis (Cat's Claw)

Cat's claw is a vine from the basin of the Amazon River. There are two species, *Uncaria tomentosa* and *Uncaria guianensis*, that are traditionally used in South America for their anti-inflammatory properties. The bark and the root are prepared as an extract in hot water. Vincaria, a standardized alkaloid-depleted aqueous extract of *U. guianensis*, administrated in combination with SierraSil, a mineral-rich clay product, inhibited both basal and IL-1β-induced $^{\bullet}$NO production and glycosaminoglycans release from human cartilage explants [213].

In a small 4-week double-blind RCT on knee OA, 100 mg of Vincaria once a day was more effective than placebo in reducing VAS of pain associated with activity but not with at-rest pain or at night [214]. There was no more adverse effect in the cat's claw group than in placebo, although cat's claw has been reported as nephrotoxic [215].

### 9.5 *Salix sp* (Willow Bark)

The anti-inflammatory, antipyretic, and analgesic effects of willow bark are known since antiquity. Willow bark contains salicin derivatives, which are rapidly metabolized in vivo to salicylic acid. The acetylated derivative of salicylic acid is known as aspirin. Willow bark extracts are usually standardized based on salicin content even if salicin might not be the major active compound. Indeed, a pharmacokinetic trial demonstrated that serum salicylate concentrations in human volunteers after oral administration of current therapeutic doses of willow bark extracts (corresponding to 240 mg salicin/day) were too low to explain a relevant analgesic effect [216], indicating that probably other active compounds are present in the extract. In fact, willow bark extract has been demonstrated to inhibit the COX-2-mediated release of $PGE_2$ as well as the release of TNF-α and IL-1β by primary human monocytes, through compounds other than salicin or salicylate [206].

In a 2-week double-blind RCT on knee and hip OA, an amount of willow bark extract (*Salix purpurea x daphnoides*) corresponding to 240 mg of salicin a day was more effective than placebo in reducing the WOMAC pain subscore but the effect size was small [216]. Another 6-week double-blind RCT comparing the effects of another willow bark extract (*S. daphnoides*) at the same dose with placebo and diclofenac 50 mg twice a day on knee and hip OA confirmed the efficacy of diclofenac but failed to detect any significant difference between willow bark and placebo on the WOMAC pain subscore [217]. In another 2-month RCT, a cocktail of 5 plants, which included 100 mg of willow bark, failed to conclusively demonstrate an analgesic effect [218]. Skin allergic reaction have been linked to *Salix* ingestion in 3–11% of the patients [219].

### 9.6 Ginger and Tumeric

The Zingiberaceae family includes ginger and tumerics. Ginger is a very popular spice with a world production of 100,000 tons a year. It is used in traditional Japanese Kampo, Ayurvedic, and Chinese medicine as an anti-inflammatory agent for musculoskeletal diseases.

In vitro, ginger extract decreased the IL-1β and LPS-induced production of $^{\bullet}$NO and $PGE_2$ by OA cartilage [220]. In synoviocyte, it decreased the IL-1β and TNF-α-induced expression of TNF-α mRNA and protein, the TNF-α-induced production of COX-2 as well as the TNF-α-induced activation of NF-κB by reducing the protein level of the NF-κB inhibitor IκB [221].

Three RCTs evaluated ginger extracts prepared from the rhizomes of *Zingiber officinale* and *Alpinia galangal*. A 3-month 3-way cross-over double-blind RCT compared the efficacy of Chinese ginger extract (EV.ext-33; 170 mg) to ibuprofen (400 mg) and placebo in knee and hip OA but failed to demonstrate a difference between placebo and ginger extract as assessed by VAS of pain and Lequesne functional index [222]. In a 6-week double-blind RCT on knee OA, 225 mg of an extract of *Z. officinale* and *A. galangal* twice a day was more effective than placebo in reducing pain on standing based on the percentage of responders [223]. Finally, in a double-blind RCT on knee OA, after cross-over at 6 months, but not at 3 months before cross-over, 250 mg of an extract of *Z. officinale* 4 times a day reduced more effectively VAS of pain and handicap than placebo [224]. In two RCTs, a higher number of adverse effects and higher drop-out rates related to gastrointestinal adverse effects (heartburn) in ginger groups have been observed [223, 224], questioning the safety of these extracts.

Curcumin (diferuloylmethane), a dietary pigment of the root of *Curcuma longa*, is a potent inhibitor (~15 μ*M*) of JNK, c-Jun, NF-κB, and JAK/STAT activation by inflammatory cytokines (oncostatin M, IL-1β, TNF-α) in primary human and bovine chondrocytes in monolayer [225, 226]. In this way, curcumin (15 μ*M*) suppressed IL-1β, OSM and TNF-α-induced MMP-3 and MMP-13 synthesis [226]. Furthermore, curcumin (50 μ*M*) counteracted the IL-1-induced inhibition of type II collagen and activation of caspase-3 synthesis in a human chondrocytes monolayer culture [227, 228].

Finally, curcumin inhibited $PGE_2$ synthesis, by down-regulating COX-2 mRNA and protein levels [229]. It was also demonstrated that, in vitro, curcumin acts synergically with celecoxib, a COX-2 activity inhibitor, to inhibit $PGE_2$ synthesis, suggesting that curcumin may enable the celecoxib at lower and safer concentrations and may pave the way for a novel combination therapy for arthritis. Its anti-inflammatory efficacy has been demonstrated in several animal models. In a rat model of adjuvant-induced arthritis, curcumin notably lowered paw inflammation in arthritic rats when administrated orally (30 mg/kg) for a period of 15 days by gavage [230].

Altogether, these preclinical results indicate that curcumin may prevent inflammation and protect cartilage from cytokine-induced cartilage matrix degradation and then might have a therapeutic potential for treating OA and related osteoarticular disorders. However, these promising preclinical results have been observed at doses 5–25 times superior to the peak concentration (~1.75 μ*M*) found in serum after oral intake of 8 g/day [231]. Curcumin is not toxic even at significantly higher doses (up to 8 g a day) [231], suggesting a possible long-term administration of this active compound.

### 9.7 Flavonoids

Flavonoids are polyphenolic compounds that are ubiquitous in nature and are categorized according to chemical structure into flavonols (quercetin, kaempferol, myricetin, Isorhamnetin), flavones (luteolin, apigenin), flavanones (hesperetin, naringenin, eriodictyol), isoflavones (ipriflavone, genistein, daidzein, glycitein, etc.), anthocyanidins (cyanidin, delphinidin, malvidin, etc.), and chalcones [(+)-catechin, (−)-epicatechin, (−)-epicatechin 3-gallate, etc.). Over 4000 flavonoids have been identified, many of which occur in fruits, vegetables, and beverages (tea, coffee, beer, wine, and fruit drinks). The flavonoids have aroused considerable interest recently because of their potential beneficial effects on human health. They were reported to exhibit estrogenic or anti-estrogenic effects, antiviral, antimicrobial, spasmolytic, antiallergic, antiplatelet [232], anti-inflammatory [233], antitumor [234], and antioxidant activities [235].

Flavonoids were shown to be potent inhibitors of several enzymes, including 5-lipoxygenase and cyclo-oxygenases [236], cyclic adenosine monophosphate (cAMP) phosphodiesterase [237], hyaluronidase [238], tyrosine protein kinase [239], deoxyribonucleic acid (DNA) topoisomerases I and II [240], and viral reverse transcriptase [241]. Our knowledge on the effects of flavonoids on chondrocyte metabolism is limited to the effect of ipriflavone. In a three-dimensional human chondrocyte culture model, 1–100 μg/mL ipriflavone did not affect chondrocyte proliferation but significantly increased proteoglycan and type II collagen synthesis [242].

Regarding isoflavones, a 3-year treatment with 129 mg/day soy phytoestrogen (SUPRO 670-HG soy protein isolate, containing 1.105 mg of genistein, 0.365 mg of daidzein, and 0.08 mg of glycitein per gm of soy protein isolate) did not significantly modify OA lesion severity and IGFBP, collagen, and proteoglycans cartilage contents in ovariectomized cynomolgus monkeys [243, 244]. A 3-month double-blind RCT on knee OA failed to show that 40 g daily of soy protein, containing a total of 88 mg of soy ipriflavones, was more effective than a milk-based protein placebo in reducing symptoms as assessed by questionnaires on pain and quality of life [245]. Soy, but not milk, protein increased serum levels of IGF-1, an anabolic factor for chondrocytes.

Catechins are found predominantly in green tea (*Camellia sinensis*) leaves [246–249]. The most abundant catechin in green tea is epigallocatechin-3-gallate (EGCG) with others such as (−)-epicatechin (EC), (−)-epigallocatechin (EGC), and (−)epicatechin gallate (ECG). Anti-inflammatory and antimitotic properties have been attributed to these compounds [250–252].

EGCG also inhibits IL-1β, TNF-α-induced cartilage matrix degradation [253] via the inhibition of IL-1-activated JNK and AP-1 pathways in human chondrocytes [254, 255], and, in consequence, the expression of MMP-1, MMP-13, but also via the inhibition of aggrecan-degrading activity ADAMTS-1, -4, and -5 [256, 257]. The inhibitory effects of EGCG on MMP expression was observed at concentrations (20–100 μ*M*) that were beyond the plasma concentrations that can be attained simply by drinking green tea (0.1–5 μ*M*) [258, 259], whereas the inhibition of ADAMTS activity was effective at concentrations (0.1–1 μ*M*) below the plasmatic concentration. Beside these anticatabolic effects, EGCG also inhibits the IL-1β-induced activity and expression of COX-2 and NOS-2 in human chondrocytes, indicating that this compound may have anti-inflammatory effects [254, 260]. EGCG also reduced the IL-1β inhibitory effect on type II collagen, aggrecan core protein, and TGF-β receptor II (TGF-bRII) mRNA levels [261].

However, until now, no study has investigated the efficacy of green tea polyphenols on OA symptoms and structural changes in human and animal studies. One animal study on collagen-induced arthritis in mice has reported that mice receiving green tea polyphenolic fraction in the drinking water before collagen injection and during the course of the study (up to 85 days) were significantly less susceptible to the development of arthritis, and, if the mice developed arthritis, the disease was late in onset and mild in comparison to mice not given green tea polyphenolic fraction in drinking water. The arthritic joint had significantly lower concentrations

of inflammatory cytokines (IFNγ, TNF-α) and other mediators of inflammation such as COX-2 [262].

### 9.8 *Boswellia serrata*

The gummy oleoresin from the bark of *Boswellia serrata*, a tree from northwest India, is used to treat inflammatory diseases in Ayurvedic medicine. This compound is known as a potent inhibitor of 5-lipoxygenase, but its effects on chondrocytes remain unknown. The clinical efficacy of a herbomineral formulation containing roots of *Withania somnifera*, the stem of *B. serrata*, rhizomes of *Curcuma longa*, and a zinc complex (Articulin-F) was evaluated in a 6-month double-blind cross-over RCT in 42 patients with OA. A cocktail of 650 mg twice a day, called Articulin-F, was more effective than placebo in reducing pain and disability scores. Radiological assessment, however, did not show any significant changes in both groups. Side effects observed with this formulation did not necessitate withdrawal of treatment [263]. In an 8-week double-blind cross-over RCT including 30 patients with knee OA, 333 mg of the gum 3 times a day was more effective than placebo in reducing knee pain, loss of movement, and swelling score and in increasing walking distance [264].

### 9.9 Cocktails of Plant Extracts

SKI306X is an herbal mixture prepared from three plants (dried roots from *Clematis mandshurica*, *Trichosantes kirilowii*, and *Prunella vulgaris*) used for the treatment of inflammatory diseases in Far East Asia. It is clinically approved for the treatment of OA in Korea.

In vitro, SKI306X and *T. kirilowii* extract, but not the other two plant extracts, reduced the IL-1α-induced GAG release from rabbit articular cartilage explant [265]. Synergistic effects between the three extracts present in SKI306X were suspected since the proportion of *T. kirilowii* was insufficient to fully explain the product potency.

In rats, SKI306X did not cause significant gastric damage up to an oral dose of 2 g/kg and suppressed the diclofenac-induced gastric damage [266]. In rabbits, 200 mg/kg/day reduced the OA-like histological changes in collagenase-injected knees [265].

In a 4-week double-blind RCT on knee OA, 200, 400, and 600 mg 3 times a day were more effective than placebo in reducing VAS of pain, with no significant difference between the three doses [267]. In another 4-week double-blind RCT on knee OA, 200 mg three times a day was not less effective than 100 mg of diclofenac sustained release once a day in reducing VAS of pain [268]. During the study, there was no statistically significant difference between the two treatment groups in the incidence of any adverse effects. However, the number of patients who had adverse events, particularly heartburn, during the study was slightly greater in the diclofenac group than in the SKI306X group.

The effects of Gitadyl, a herbal formulation containing extracts from feverfew, American aspen, and milfoil, at a dose of 260 mg three times a day were compared to the effects of 400 mg of ibuprofen three times a day in a 42-day double-blind cross-over RCT. Both treatments failed to significantly change the pain and patients' ability to walk as assessed by four-point scales [269].

In a 4-week double-lind RCT on knee OA, 3 g, 3 times a day, of Duhuo Jisheng wan, a traditional Chinese cocktail of 15 plants improved the Lequesne functional index and multiple VAS of pain and stiffness as effectively as 25 mg of diclofenac, three times a day [270]. Duhuo Jisheng wan had a slower onset of action than diclofenac but an equal rate of adverse events, an observation that questions its safety.

## 10 METHYLSULFONYLMETHANE

Methylsulfonylmethane (MSM) is the first oxidized metabolite of dimethylsulfoxide (DMSO) and a putative methyl donor. DMSO is found in fruit, corn, tomatoes, tea, coffee, and milk. MSM has been isolated from plants such as *Equisetum arvense*, also known as horsetail. In commercial production, MSM is synthesized by reacting DMSO and hydrogen peroxide, which yields MSM and water. MSM is currently sold in over 52 different products as a single agent in capsule, caplet, lotion, and cream forms and in more than 30 different products in combination with other dietary supplements, mainly GS and CS. There is little information on the mechanism of action of MSM. MSM has been demonstrated to be a strong scavenger in numerous free-radical-generating systems. Clinical evidence for the usefulness of MSM in OA is limited to two short pilot studies. In a 12-week double-blind placebo-controlled RCT on knee OA, 500 mg of MSM, 3 times a day, combined or not with 500 mg of glucosamine-HCL, 3 times a day, significantly improved symptoms (VAS of pain and Lequesne functional index) [271]. In this study, both glucosamine-HCL and MSM improved OA symptoms, but when taken together the effect was greater than either alone. This beneficial effect has been recently confirmed in a double-blinded RCT including 50 patients with knee OA [272]. Compared to placebo, MSM (3 g twice a day for 12 weeks) produced modest, but significant, decreases in WOMAC pain and physical function impairment, while no changes were found in WOMAC stiffness and aggregated total symptoms

scores. MSM also produced improvement in performing activities of daily living when compared to placebo on the SF-36 evaluation. No evidence of a more general anti-inflammatory effect was found, as there were no significant changes in two measures of systemic inflammation: C-reactive protein level and erythrocyte sedimentation rate. The authors cautioned that this short pilot study did not address the long-term safety and usefulness of MSM but suggested that physicians should consider its use for certain OA patients, and that long-term studies should be conducted [272]. MSM is generally considered safe, even though there are no clinical studies on adverse effects. Nevertheless, in the two published RCT, no severe adverse effects have been reported.

## 11 MISCELLANEOUS

### 11.1 Biphosphonates and Strontium Ranelate

The rationale to use biphosphonates to treat OA was provided by the recent findings that subchondral bone remodeling plays a role in the progression of OA pathogenesis. Biphosphonates, mainly the nitrogen-containing biphosphonate, inhibit bone resorption by increasing osteoclast apoptosis [273] and by inhibiting their resorptive function (for more details see [274]). Furthermore, biphophonates inhibit calcification by binding to the surface of solid calcium phosphate crystals and acting as crystal poisons affecting both crystal growth and dissolution [275]. These findings suggest that biphosphonates could be beneficial in OA treatment, by restoring subchondral bone homeostasis and by preventing cartilage mineralization. In addition, biphosphonates induce macrophage apoptosis, suggesting that they could have an anti-inflammatory effect. In animal models, encapsulated chlodronate was found to reduce the number of macrophages and to reduce inflammation [276]. When a single intra-articular injection of encapsulated chlodronate was given to patients with RA, a depletion of synovial macrophages was observed [277].

Numerous animal studies of arthritis have suggested that biphosphonates may have chondroprotective abilities [278–281]. The most recent study [280] showed a reduction of cartilage degeneration, as determined by histologic criteria, and prevention of osteophyte formation by alendronate in a rat anterior cruciate ligament transection model. Alendronate suppressed subchondral bone resorption, inhibited vascular invasion into the calcified cartilage, and blocked osteoclast recruitment to subchondral bone and osteophytes. Two recent studies have demonstrated that treatment with biphosphonates (alendronate and zoledronate) decreased the urinary concentration of CTX-II, a marker of cartilage degradation, suggesting that biphosphonates may have chondroprotective effects in human [282, 283]. However, these studies suffer from some limitations, including short follow-up period, the lack of arthritis assessment procedures, or the absence of correlation between CTX-II levels and cartilage structural changes. More recently, a 1-year prospective, double-blind, placebo-controlled study, including mild to moderate OA of the medial compartment of the knee, has been designed to determine the efficacy of risedronate (5–15 mg/day) in structure and symptoms of knee OA [284]. The study showed that patients receiving 15 mg of risedronate had an improvement of the WOMAC index, particularly of physical function, significantly improved the total patient assessment, and decreased use of walking aids relative to patients receiving a placebo. While the differences in joint space width among the groups were not significant, there was a trend for less loss in the risedronate (15 mg) than in the placebo group. When data were analyzed in a post hoc manner to identify patients with detectable progression (i.e., loss of JSW ≥25% or ≥0.75 mm), 8% of the patients receiving placebo and 1% of patients receiving 15 mg risedronate were found to exhibit this degree of progression. Additionally, risedronate significantly reduced levels of CTX-II, but this was not associated with an attenuation of joint space loss.

Strontium ranelate (S12911), an uncoupling agent developed as a preventive and curative treatment of postmenopausal osteoporosis [285], prevents bone loss induced by estrogen deficiency by inhibiting bone resorption and stimulating bone formation [286]. In vitro, strontium ranelate increases collagen and noncollagen protein synthesis by mature osteoblast-enriched cells. Its effects on bone formation were confirmed as the drug-enhanced preosteoblastic cell replication. In the isolated osteoclasts, preincubation of bone slices with strontium ranelate induced dose-dependent inhibition of the bone resorbing activity of rat osteoclasts [287]. Strontium ranelate dose-dependently inhibited preosteoclast differentiation. Recently, we have studied the effects of strontium ranelate, calcium ranelate, and strontium chloride on the metabolism of primary human OA chondrocytes in a suspension culture [288]. We have observed that strontium ranelate, calcium ranelate, and $SrCl_2$ did not modify stromelysin synthesis. Calcium ranelate induced stromelysin activation, whereas strontium compounds were ineffective. Strontium ranelate, $SrCl_2$, and calcium ranelate strongly stimulated aggrecan production suggesting an ionic effect of strontium independent of the organic moiety. Morever, strontium ranelate increased the stimulatory effect of insulin-like growth factor (IGF)-1 on aggrecan synthesis but did not reverse the inhibitory effect of IL-1β. In summary,

strontium ranelate strongly stimulates human cartilage matrix formation in vitro by a direct ionic effect without stimulating the chondroresorption processes. This finding provides a preclinical basis for in vivo testing of strontium ranelate.

### 11.2 Diacerhein

Diacerhein is an anthraquinone that is entirely transformed by deacetylation during absorption into rhein, the active metabolite found in plasma and synovial fluid [289, 290]. In vitro, rhein inhibits the production of MMPs and stimulates the production of aggrecan by human OA chondrocytes [291, 292]. It also counteracts the effects of IL-1β on MMPs and aggrecan. These positive effects of rhein on cartilage matrix formation are explained by its stimulating effect on TGF-β1 and -β2 gene expression and by its inhibiting action on IL-1β secretion [293, 294]. Furthermore, rhein was demonstrated to downregulate $^{\bullet}$NO production by human OA chondrocytes in alginate beads [291], in monolayer [295], and in cartilage explants [296]. The effect of rhein appeared to result from iNOS transcriptional and/or posttranscriptional events, as indicated by a decrease in the levels of mRNA and protein for this enzyme in human OA chondrocytes [296]. Rhein was also demonstrated to decrease arthritis activity and $NO_2^-$ level in the plasma of rats with adjuvant-induced arthritis. These data suggest that the inhibitory effect of diacerein on rat-adjuvant-induced arthritis is partly related to its reduction of the $^{\bullet}$NO production induced by adjuvant-induced arthritis [292]. However, in some in vitro systems, rhein may also exhibit a pro-oxidant effect that could be responsible for its cellular toxicity [297, 298]. This problem was underestimated in some in vitro studies reporting the effect of rhein on chondrocytes. At concentrations over $10^{-5}$ *M*, rhein induced cytotoxicity in human chondrocyte [291]. One possible mechanism underlying this toxic effect is that rhein undergoes redox cycling that gives rise to oxygen metabolites that initiate peroxidation of cellular membrane [297].

In well-known and validated animal models of OA induced by vitamin A [299], postcontusion and postpatellectomy OA [300], diacerhein was demonstrated to prevent the development of OA. In these models, diacerhein was shown to be active in reducing macroscopic and microscopic lesions, in preventive and therapeutic ways. However, the exact mechanisms of the therapeutic action of diacerhein on OA are not clear. In an accelerated canine model of OA in which sensory input from the ipsilateral hind limb was interrupted by L4-S1 dorsal root ganglionectomy prior to cruciate ligament (ACL) transaction, diacerhein (15–20 mg/kg once daily for 8 weeks) did not significantly modify the severity of cartilage lesions, the collagenolytic activity and the proteoglycan level contained in OA cartilage [301]. In a less rapidly progressive canine model, in which OA was induced by ACL only, diacerhein (40 mg/kg for 8 months) has been shown to slow down the progression of cartilage lesions as estimated by an arthroscopic grading scale [301]. However, 32 weeks after ACL transection, the mean proteoglycan concentration of the OA cartilage and the level of collagenolytic activity in cartilage extracts were not significantly different in the diacerhein group compared to placebo. In an ovine model of OA induced by menisectomy, diacerhein (20–50 mg/kg daily for 9 months) failed to significantly improve the gross morphological and histological severity of cartilage lesions [302].

In several randomized, double-blind, placebo-controlled clinical trials of 2–6 months duration, diacerhein significantly reduced the pain and functional impairment in patients with hip or knee OA [299, 303, 304]. Recently, a 3-year, placebo-controlled trial (ECHODIAH) including 507 patients with primary OA of hip has demonstrated that the occurrence of radiographic progression (i.e., joint space narrowing measured by a graduated magnifying lens) of at least 0.5 mm during the study was significantly lower and occurred later in the diacerhein (100 mg daily) as compared with the placebo group [305].

### 11.3 Doxycycline

Doxycycline is a member of the tetracycline family of broad-spectrum antibiotics. During the last decade, it has been established that tetracyclines, which are rapidly absorbed and have a prolonged half-life, exert biological effects independent of their antimicrobial activity, which include inhibition of MMPs [306], NOS expression [307], tumor progression [308], bone resorption [309], angiogenesis [310], and inflammation [311]. Among these effects, some could have a beneficial effect on OA pathophysiology. In human OA cartilage, doxycycline (10–40 μg/mL) inhibited $^{\bullet}$NO production and augmented COX-2 and $PGE_2$ production (one- to two-fold) in the absence or in the presence of IL-1β and TNF-α or LPS. Thus, the effects of docycycline on $^{\bullet}$NO and $PGE_2$ production were independent of each other [307, 312, 313]. Doxycycline (1–10 μg/mL) also decreased levels of mRNA and protein of MMP-1, MMP-8, and MMP-13 in TNF-α-stimulated human normal and OA chondrocytes [314]. Beside this anticatabolic effect, doxycycline ($IC_{50} = 25\,\mu M$) inhibited collagens, including type II collagen, and the synthesis by bovine and human chondrocytes [315]. Beekman et al. also reported that the concentration of doxycycline needed to down-

regulate collagen synthesis was >10-fold lower than that needed to inhibit most of MMPs.

In dogs, that underwent L4-S1 dorsal root ganglionectomy followed by ipsilateral anterior cruciate ligament transection, a procedure that markedly accelerates development of OA in the unstable joint, prophylactic and therapeutic oral administration of doxycycline (roughly 3.5 mg/kg/day) significantly retarded the appearance of cartilage lesions [316] via inhibition of MMPs [317] and probably through an effect on subchondral bone [318]. Recently, it was demonstrated that 36 weeks of treatment with doxycycline (4 mg/kg/day) had beneficial effects on structural and mechanical changes observed on the superficial (0–3 mm) but not the deeper zones (4–5 mm) of the subchondral bone in late OA induced surgically by ACLT [319].

Five days of doxycycline treatment, in a dose of 100 mg bid, reduced collagenase and gelatinase activities in human OA cartilage ex vivo, while a single 200-mg dose, given 3 days before taking cartilage sample, was ineffective in inhibiting MMP activity [320]. Brandt and his colleagues [321] have shown that treatment with oral doxycycline can slow the rate of joint space narrowing in the index knee OA of obese women over a 30-month period. There were no significant effects on pain, but there was a small group difference in other clinical outcomes that favored those treated with doxycycline over those treated with placebo [321].

## 12 CONCLUDING REMARKS

Osteoarthritis is a disease with a multifactorial etiology affecting all joint tissues and involving both biochemical and mechanical factors that act in synergy to degrade cartilage. Until now, OA treatments are limited to pain relief, even if some new drugs of the SYSADOA class have shown potential structure-modifying effects. These drugs target cartilage as the endpoint of joint failure, underestimating the role played by subchondral bone and synovium in this process. However, recent studies emphasized the key role played by subchondral bone sclerosis and synovium inflammation in OA pathophysiology. Unfortunately, until now, there is no validated method for a reliable assessment of structural changes in these tissues, explaining that guidance documents edited by the official agencies and scientific societies are strictly focused on the assessment of cartilage changes. Actually, pharmacological management of OA is dominated by analgesic, NSAIDS, and SYSADOA, which constitute a new class of drugs characterized by slow action on OA symptoms and good tolerability. Some SYSADOAs are nutraceuticals (e.g., glucosamine or chondroitin sulfate) and are provided as dietary supplements or prescribed drugs according to the country and the product specifications. The absence of a clear definition and a requirement for registration of nutraceuticals throws the scientists and practitioners into confusion. Often data coming from preclinical and clinical studies of prescribed drugs are extrapolated to over-the-counter products that differ considerably in source, formula, purity, rhythm, and dose administrated. Actually, more than 30 nutraceutical products are marketed as potentially active in OA but few have demonstrated their efficacy and safety in human clinical trials. Clearly, in terms of regulations, there is a need to resolve the general confusion about whether nutraceuticals are food supplements or medicines.

# DEVELOPMENT OF ANTICYTOKINE AGENTS FOR RHEUMATOID ARTHRITIS

Jonathan Sherlock, Christopher D. Buckley, and Karim Raza

*Rheumatology Research Group, MRC Centre for Immune Regulation, University of Birmingham, Birmingham, United Kingdom*

## 1 INTRODUCTION

Rheumatoid arthritis (RA) is a common systemic inflammatory disease [1] characterized by joint destruction and extra-articular inflammation, resulting in severe morbidity and increased cardiovascular mortality [2]. The past decades have witnessed the gradual development of orally administered immunomodulatory treatments with methotrexate and sulfasalazine being the most frequently used nonbiological agents in the United Kingdom. Experience with these drugs has resulted in the concept of "disease-modifying" anti-rheumatic drugs (DMARDs), which can be introduced early after a diagnosis of RA has been made to reduce the rate of progression of joint damage.

Despite the success of methotrexate and other disease-modifying agents, many patients with RA fail to respond adequately to these drugs. This might be because these drugs have been used too late, at the wrong dose, or more likely because they do not adequately target the right disease processes. Recent years have witnessed the exciting development of biological therapeutics that use antibody or protein technology to target, with high specificity, particular molecules involved in the inflammatory pathway, thus disrupting the cellular communication necessary for the orchestration of inflammation. Their use in combination with traditional DMARDs has led to highly effective gold standard treatments in which clinical remission has at long last become possible [3–5].

## 2 CASE STUDY: ANTI-TNF AGENTS

Neutralization of tumor necrosis factor (TNF) was the first example of specific targeting of a cytokine in RA [6], and its enormous success has meant it is now available as part of routine clinical practice. The identification of TNF as a clinically relevant target highlights several concepts central to any discussion of the development of anticytokine agents. Though the subject of several reviews by Feldmann and Maini who pioneered this field [6, 7], the key points are summarized below.

While work by Feldmann's group demonstrated that multiple cytokines were present in the rheumatoid synovium, it was initially suspected that their number was so great and function so redundant that the neutralization of only one cytokine would have a minimal effect on inflammation [6, 7]. Interleukin-1 (IL-1) was viewed as a key molecule of interest, since it exhibited prolonged expression in cultures of rheumatoid synovial cells, in contrast to its transient expression in models of infection where the inflammation resolved [6]. The concept thus emerged that the dysregulated, chronic production of cytokines was responsible for the persistent inflammation seen in RA [6, 8]. The key observation came when an anti-TNF antibody was added to rheumatoid synovial cell cultures resulting in cessation of IL-1 production [6, 9]. When it was later demonstrated that the neutralization of TNF also led to reductions in other inflammatory molecules such as IL-6 and IL-8, the concept emerged that TNF was a master

regulator sitting at the apex of a hierarchy of inflammatory cytokines [6, 7]. Further evidence for the importance of TNF came from the observation that both TNF and its receptor were upregulated in biopsies of rheumatoid tissue [10], and that neutralization of TNF in mice resulted in amelioration of disease in an inflammatory arthritis model [11], whereas transgenic expression of TNF resulted in a destructive polyarthritis [12].

Subsequent clinical trials demonstrated that the chimeric anti-TNF antibody infliximab resulted in a dramatic reduction in disease activity, improvement in physical function, reduction in inflammatory markers such as C reactive protein (CRP) and cytokines such as IL-1 and IL-6, as well as an inhibition of angiogenesis and a slowing of the rate of joint erosion [13–16]. Following treatment with infliximab, synovial membrane biopsies demonstrated reduced cellularity [6], and the observation that the drug results in reduced articular retention of radio-labeled leukocytes demonstrated that neutralization of TNF-modified cell trafficking [17].

Despite the enormous success of infliximab, and other agents such as etanercept and adalimumab, which also target TNF, the use of this class of drugs is associated with an increased risk from specific infectious agents, in particular *Mycobacterium tuberculosis* [18], and is rarely associated with development of other autoimmune diseases [19]. Furthermore, a significant proportion of patients do not respond to TNF-neutralizing agents. These problems have fueled the search for a better understanding of the cellular and molecular pathogenesis of RA in order to identify alternative targets for neutralization.

## 3 NOVEL THERAPIES TARGETING CYTOKINES

Study of the rheumatoid synovium reveals it to be a highly activated tissue in which multiple cell types are present and multiple cytokines are expressed. This tissue contains activated macrophages, mast cells, fibroblasts, endothelial cells, and lymphocytes bathed in a rich cocktail of inflammatory cytokines. It is apposed to bone on which sit activated osteoclasts that actively resorb the bony surface. The expansion of these synovial cell populations is facilitated by the neovascularization that is a hallmark of the rheumatoid synovium.

Recent years have seen the identification of several new cytokines within the inflamed rheumatoid joint. We have chosen to focus our review on several representative agents that demonstrate therapeutic promise and shed particular light on pathogenic mechanisms operating in chronic inflammatory disease. For example, we will demonstrate how IL-15 has emerged as a key cytokine involved in chronicity of inflammation through the promotion of memory T-cell survival, how IL-18 allows T cells to produce cytokines independently of stimulation via the T cell receptor (TCR) and thus fosters antigen-independent inflammation, and how the IL-23/IL-17 pathway demonstrates that autoimmune inflammation proceeds by a mechanism different from that of the IL-12/IFNγ (interferon gamma) pathway classically associated with resistance to common infections.

## 4 INTERLEUKIN-15

IL-15 is a 14- to 15-kDa member of the four-α-helix bundle cytokine family [20], initially discovered as a molecule with T lymphocyte and natural killer (NK) cell activating properties and structural homology to IL-2 [21, 22]. It is produced by monocytes, macrophages, dendritic cells, epithelial cells, and fibroblasts [23–29], and its receptor shares the common $\gamma_c$ chain with the receptors for IL-2, IL-4, IL-7, IL-9, and IL-21. However, it is the unique IL-15Rα chain, to which IL-15 binds with high affinity, that is critical for its effect in vivo. Interestingly, this receptor has an unusual mechanism of action—instead of IL-15 being simply secreted from cells, it is expressed on the cell membrane bound to IL-15Rα, which presents the cytokine in *trans* to neighboring cells such as $CD8^+$ T cells and natural killer (NK) cells, which express only the IL-2/IL-15Rβ and $\gamma_c$ chain [30]. While the IL-15/IL-15Rα complex undergoes transendosomal recycling, its stability and constant reappearance on the cell membrane allows persistent activity. In keeping with this mechanism of action, coordinate expression of IL-15 and IL-15Rα on the surface of monocytes and dendritic cells is facilitated by shared promoter elements in these two genes conferring response to interferons and signals from Toll-like receptors (TLRs) [31–33]. Consistently, in vivo mouse models had demonstrated a requirement for IL-15Rα on antigen presenting cells (APCs), rather than on responding T or NK cells, before elucidation of this model [34].

IL-15 plays a key role in the promotion of NK cell [35], natural killer T (NKT) cell, and CD8 memory lymphocyte homeostasis. Thus transgenic mice overexpressing IL-15 have raised numbers of these cells, and their survival is augmented by the ability of IL-15 to inhibit IL-2-induced activation induced cell death (AICD) [36]. Conversely, IL-15- or IL-15Rα-deficient mice are lymphopaenic with reduced mature lymphocytes—particularly the CD8 subset—secondary to defective homing and proliferation [34, 37]. Despite being in the same cytokine family, IL-15 and IL-2 have

opposite effects on memory T cells, survival of which is supported by IL-15 but suppressed by IL-2 [38]. The importance of T cells in the rheumatoid joint is demonstrated by the therapeutic benefits of drugs targeting T-cell activation, such as ciclosporin, and the association of RA with certain human leukocyte antigen (HLA) alleles. Given the ability of IL-15 to maintain memory T cells and thus its potential to maintain chronic inflammation, this cytokine represents a key target for investigation in RA.

Indeed, despite being a predominantly membrane-bound cytokine, raised levels of IL-15 have been detected in serum and synovial fluid in RA patients compared to individuals with osteoarthritis (OA) [27, 39, 40] and levels have been found to rise with disease duration [41]. Moreover, IL-15 is also present in rheumatoid nodules [42]. While expression in fibroblast-like synoviocytes and endothelial cells has been observed, lining layer macrophages are the main cellular source of IL-15 in RA [27–29]. IL-15 is chemotactic to T cells and increases their transendothelial migration [27, 29, 43], thus acting as a potent agent recruiting cells of the $CD45RO^+$ memory group [44]. The importance of this function in RA in vivo has been emphasized by experiments showing that IL-15 leads to accumulation of T cells in human RA synovium engrafted into severe combined immunodeficient (SCID) mice [29], and the inflammatory infiltrate induced by injection of IL-15 into the hind foot pads of mice primed with *Corynebacterium parvum* consists of cells just over half of which express CD3 [27]. The stimulatory effects of IL-15 on memory cell numbers, promotion of their proliferation [38, 45] and inhibition of AICD [36], as well as *Bcl-2*-mediated inhibition of T-cell apoptosis [25], suggests that the high expression of this cytokine in RA could contribute to loss of tolerance and chronicity of inflammation by promoting survival of autoreactive T cells, as well as stimulating their homing to the synovium.

Moreover, as well as its effects on memory T lymphocytes, IL-15 has strong pro-inflammatory actions on cells of the innate immune system, stimulating cytokine production and the oxidative burst by macrophages and neutrophils, and granule release from the latter [46] as well as activating dendritic cells [47]. Furthermore, it activates fibroblasts to proliferate and upregulate Bcl-2 and Bcl-$X_L$ [48], and secrete cytokines and matrix metalloproteinases (MMPs) [49]. IL-15 critically links T cells with the innate immune system, since T cells activated with this cytokine induce TNF production by blood- or synovium-derived macrophages in a cell contact-dependent manner [39], and this may contribute to a positive feedback loop in which activated macrophages express IL-15, contributing to further T-cell chemoattraction, resulting in further stimulation of macrophages to produce TNF. Given the recent identification of the critical role played by IL-17 in autoimmune joint inflammation [50], it is noteworthy that IL-15 stimulates IL-17 production in a cyclosporine–sensitive way [51], and IL-17 in turn induces stromal cells [52] and macrophages [53] to produce inflammatory cytokines.

Given the newly emphasized role of B lymphocytes in RA, following from the therapeutic success of the B-cell-depleting antibody rituximab, the effects of IL-15 on B lymphocytes are of great interest. The cytokine induces their proliferation and isotype switching [54], and in animal models where IL-15 is targeted, the production of collagen-specific $IgG_{2a}$ antibodies is delayed [55]. This aspect of IL-15 biology requires further elucidation.

Animal models have confirmed the importance of IL-15 in autoimmune inflammation in vivo. In particular, in the collagen induced arthritis (CIA) model, administration of IL-15 with incomplete Freund's adjuvant during priming with type II collagen resulted in an inflammatory and erosive arthritis in DBA/1 mice, which closely resembled that in mice primed with complete Freund's adjuvant [56]. Binding of IL-15 by administration of a soluble IL-15Rα suppressed CIA, with reduced TNF production and delayed formation of collagen-specific $IgG_{2a}$ antibodies [55]. Moreover, using an antagonistic mutant IL-15/Fc fusion protein, Ferrari-Lacraz et al. have shown that this agent not only inhibits the onset of CIA but also blocks disease progression in established arthritis, reduces synovitis, bone erosion, and cartilage destruction, as well as decreasing intra-articular expression of TNF, IL-1β, IL-6, and IL-17 [57]. Of particular note, the responder frequency of autoreactive T cells was reduced not only in vitro but in vivo as assessed by carboxyfluorescein succinimidyl ester (CFSE) staining of splenocytes. Remarkably, after withdrawal of the agent, sustained clinical remission was obtained. This suggests that inhibition of the IL-15 pathway, coupled with possible FcR-mediated destruction of IL-15R expressing cells by the Fc component of the reagent, hinders the perpetuation of autoreactive T cells. The cytocidal properties of the reagent are critical, since remission was not observed with IL-15 blockade using the soluble IL-15Rα.

A recent phase I–II clinical trial of the human $IgG_1$ anti-IL-15 antibody HuMax-IL-15, demonstrated that the drug was well tolerated and had no significant effect on NK or T-lymphocyte subset numbers. Substantial clinical improvements were seen, as measured by the American College of Rheumatology criteria for 20% improvement (63% of patients), 50% improvement (38% of patients), and 70% improvement (25% of patients) [58].

Therapeutics targeting IL-15 thus show promise, and it will be of great interest to establish if subgroups of patients who are unresponsive to currently used TNF-based drugs might benefit from neutralization of IL-15.

## 5 INTERLEUKIN-18

IL-18 was discovered as a molecule that stimulates IFNγ production from splenocytes and $T_h1$ cells and is produced in the livers of mice treated with *Propionibacterium acnes* and lipopolysaccharide (LPS) [59–62]. Although its biology is strongly reminiscent of that of IL-12, IL-18 has no protein or nucleotide sequence similarity to the IL-12 family. Initial structural-based comparisons, which suggested that it is part of the IL-1 cytokine family [63], have been confirmed, and indeed IL-18 processing as well as its receptor and signal transduction system are analogous to the IL-1/IL-1R and related TLR system [64]. While this may suggest its place in an evolutionarily ancient system capable of activating innate immunity, most attention has focused on the ability of IL-18 to enhance IL-12-mediated $T_h1$ cell activation and IFNγ production.

IL-18 is produced by macrophages [62, 65, 66] and dendritic cells [67] and stimulates IFNγ production by T cells and NK cells as well as enhancing their cytotoxicity. Indeed, for maximal production of IFNγ, human T cells require both IL-12 and IL-18 [64], and in mice each cytokine upregulates the other's receptor [68, 69]. While IL-12 stimulated T-cell production of IFNγ, which usually requires TCR-mediated T-cell activation, the addition of IL-18 not only causes more IFNγ production than addition of excess IL-12 [61] but allows its production in a manner independent of TCR stimulation [70–72]. This is confirmed by the observation that cyclosporine, an inhibitor of TCR-derived signaling, does not inhibit this effect, nor does immobilized anti-CD3 enhance it [72, 73]. This may contribute to chronicity of inflammation by licensing T cells to produce pro-inflammatory cytokines independent of stimulation by their cognate antigen. Additionally, IL-18 activates a distinct "helper" subset of NK cells that produce high levels of IFNγ [74]. Moreover, the important role played by antigen-presenting cells themselves in production of IFNγ has been increasingly appreciated [75], and IL-18 is important in this process. Bone-marrow-derived macrophages produce IFNγ in response to IL-12 and IL-18 stimulation [76], as do dendritic cells [77] and B lymphocytes [78].

IL-18 is found at raised levels in the serum and synovial fluid of RA patients compared with those with OA, and ex vivo synovial fluid samples from RA patients stimulate IFNγ production in an IL-18-dependent manner [79, 80]. Macrophages purified from rheumatoid synovium are able to release IL-18 protein [80], and IL-18 expression is observed in $CD68^+$ macrophages and fibroblast-like synoviocytes, while the IL-18Rα has been demonstrated on synovial T cells and macrophages. IL-18 expression correlates with macrophage infiltration, microscopic inflammation score, erythrocyte sedimentation rate (ESR), and local production of IL-1β and TNF in the synovium [81]. IL-18 upregulates production of the inflammatory molecules granulocyte monocyte colony stimulating factor (GM-CSF) and nitric oxide and operates in positive feedback with TNF, since both IL-18 and TNF upregulate each other's production [79]. This is clinically important, since treatment with infliximab has been shown to reduce the serum concentration of IL-18 as early as 2 weeks after treatment, and the change in IL-18 correlates with the clinical response, suggesting that reduction in IL-18 may be an important component of the action of anti-TNF agents [82, 83]. IL-18 has additional prodegradative effects on articular cartilage—it is induced in chondrocytes by IL-1β and upregulates the destructive enzymes cyclooxygenase 2 (COX2) and inducible nitric oxide synthase (iNOS), and stromelysin in an IL-1β-independent manner [84], while reducing the proliferation of chondrocytes. Indeed, application of IL-18 to normal human cartilage results in the release of glycosaminoglycans.

The pro-inflammatory role of IL-18 in autoimmune joint inflammation has been confirmed in vivo by the reduced incidence and severity of CIA in *IL-18* knockout (KO) mice [85]. Moreover, whereas immunization of DBA/1 mice with collagen and incomplete Freund's adjuvant (IFA) is usually unable to induce CIA, concomitant administration of IL-18 induces CIA, which is histologically indistinguishable from that induced with complete Freund's adjuvant (CFA), and this treatment with IL-18 augments expression of TNF and IL-6 [86]. These studies have been extended by the development or reagents to block the in vivo function of IL-18. Single administration of an anti-IL-18 antibody or daily injections of IL-18BP both resulted in a delay in arthritis and prevention of cartilage destruction; however, only the antibody caused significant reduction in joint inflammation and cell infiltration, emphasizing the importance of the mechanism of action of IL-18 neutralizing reagents in the outcome [87]. A different approach has used intra-articular adenoviral-mediated gene expression of murine IL-18BP, which reduces both severity and incidence of arthritis and synovial inflammation and prevents bone erosion and cartilage destruction [88].

Given the recent realization that CIA is critically dependant on IL-23-induced $T_h17$ cells, rather than IL-12-induced $T_h1$ cells between which there is a mutual antagonism [50], it is important to re-evaluate the con-

tribution of the direct pro-inflammatory effects of IL-18 and those mediated via IFNγ, since the latter might be expected to be less important, at least in the mouse system. Indeed, it has been observed that IL-18 treatment of mice, while inducing TNF and IL-6, caused less IFNγ production than did treatment with IL-12 [86], emphasizing the dominant role of IL-12 in the induction of $T_h1$ cytokine responses. The importance of the IFNγ pathway in joint inflammation is again questioned by the observation that despite the high level of expression of IL-18 in RA synovial membranes, there is a relative lack of IFNγ and IL-12 expression [89]. This may be secondary to antagonism by a dominant IL-17 pathway in the joint. Moreover, it has been emphasized that IL-18 is not an exclusive stimulator of $T_h1$ cells, as in the absence of IL-12, it can promote $T_h2$ differentiation and allergic inflammation [64]. It will, therefore, be of great interest to determine any role it plays in $T_h17$ lymphocyte biology.

Thus the importance of IL-18 in RA may result from its direct IFNγ-independent effects, such as its ability to increase chemokine expression [90], upregulate Fas ligand-mediated cytotoxicity of NK [91] and T cells [92], and induce nuclear translocation of nuclear factor of kappa light polypeptide gene enhancer in B-cells (NF-κB) [93]. IL-18 directly upregulates TNF production by splenic macrophages [86] and stimulates the release of IL-1β and IL-8 from $CD14^+$ cells, in a process dependent on its ability to stimulate TNF production from T and NK cells [90].

IL-18 plays two roles in vascular biology of relevance to its therapeutic targeting in rheumatoid arthritis. Given the importance of angiogenesis in RA [94–96], the characterization of IL-18 as an angiogenic mediator [97] that can stimulate synthesis of MMPs and promote matrix breakdown [84] suggests that this is another mechanism whereby its inhibition may ameliorate joint inflammation. Furthermore, IL-18 also has been shown to be a major mediator of atherosclerosis and to contribute to plaque instability [98–101]. In view of the increased atherosclerotic risk associated with RA and other autoimmune diseases [102], it will be of great interest to determine if this is reduced by targeting of the IL-18 pathway.

One significant concern with the use of therapies targeting IL-18 is the potential to increase susceptibility to infection in the recipient. In particular, IL-18 plays a key role in immunity to multiple pathogens, including bacteria, viruses, fungi, and protozoa [64].

## 6 INTERLEUKIN-6

IL-6 was initially discovered as a B-cell differentiation factor [103, 104], but it is now appreciated to be a pleiotropic cytokine that plays key roles in hematopoiesis, the acute phase response and inflammation [105, 106]. It induces T-cell proliferation, macrophage and cytotoxic T-cell differentiation, and immunoglobulin production by B lymphocytes. Administration of IL-6 to humans causes fever and leukocytosis [107], and transgenic mice overexpressing human IL-6 develop plasmacytosis, hypergammaglobulinaemia, an increase in acute phase reactants and low albumin, and increased bone marrow megakaryocytes [108], all of which are very reminiscent of the findings in patients with RA. Moreover, IL-6 in the presence of soluble IL-6R triggers differentiation of osteoclasts, and can be responsible for the joint erosion and osteoporosis associated with RA [109, 110]. IL-6 is also a pivotal cytokine in triggering increased vascular endothelial growth factor (VEGF) production, in synergy with TNF or IL-1β [111], thus supporting the angiogenesis that is crucial for the development of synovial hyperplasia.

The multiple roles of IL-6 in the pathogenesis of RA suggested by all of these observations is supported by the demonstration that IL-6 promotor polymorphisms are associated with disease activity. In particular, a certain allele predisposes to worse disease as measured by an increased number of swollen and tender joints, raised disease activity score (DAS28), and a high ESR [112]. Furthermore, serum levels of IL-6 are closely correlated with clinical measures of RA disease activity [113] and radiological joint damage [113–116], and a correlation of synovial fluid IL-6 level with the histological characteristics of chronic synovitis suggests an important local role for IL-6 [115].

Strong support for the importance of IL-6 in vivo comes from the demonstration that IL-6 KO mice are resistant to CIA [117, 118], and the absence of IL-6 prevents the spontaneous autoimmune joint inflammation normally observed in SKG mice. Moreover, the resistance of the latter mice to joint inflammation is greater than in TNF or IL-1 KO mice [119]. Conversely, a mutation in mice of the cytoplasmic tail of the gp130 component of the IL-6 receptor complex, which interfers with binding of a negative regulator of signaling Src homology domain protein tyrosine phosphatase 2 (SHP2) and thus allows increased signaling, is associated with a spontaneous arthritis that displays great similarity to human RA on histological and radiological grounds [120]. It has been noted that antibodies to IL-6 result in the formation of monomeric immune complexes [121], and indeed efforts to develop therapeutics have concentrated on agents targeting the IL-6R. Treatment of mice with an anti-IL-6R antibody reduced the incidence and severity of CIA, and inhibited both the proliferative response of lymphocytes to collagen and the development of collagen-specific antibodies [122].

The humanized antibody tocilizumab has been developed to target the IL-6R in RA [123]. A phase II multicenter, placebo-controlled trial has demonstrated a dose-dependent improvement in disease activity, with 57% of patients receiving 4 mg/kg and 78% of those receiving 8 mg/kg showing an improvement greater than or equal to 20% according to the American College of Rheumatology (ACR) criteria [124]. Furthermore, serum markers of bone formation were increased, and urinary markers of bone absorption were decreased, suggesting that IL-6 blockade resulted in improved bone metabolism, which may prevent the osteoporosis associated with RA. A subsequent study has demonstrated that tocilizumab delays radiographic progression of joint disease in RA patients in a manner superior to DMARD treatment [125].

The benefits of blockade of IL-6 are much more widespread than those accrued at the level of the joint, with multiple improvements in systemic features of RA. As expected from the known contribution of IL-6 to the acute-phase response, treatment with tocilizumab is associated with improvement in the platelet count and in hemoglobin, fibrinogen, and albumin levels. Of interest is the reduction in serum amyloid A levels following treatment, since this therapy may induce regression of amyloid deposits, a serious complication of RA that can be difficult to treat [126]. The improvement in hemoglobin level following IL-6 neutralization may result from a reduced expression of the suppressor of cytokine signalling (SOCS) molecule, which is induced by chronic stimulation of the IL-6R to dampen signaling, but that also dampens signaling via the erythropoietin receptor, which shares the janus kinase (Jak)–signal transducer and activator of transcription (STAT) pathway with the IL-6R [127]. Another mechanism responsible for the improvement in anemia following treatment with tocilizumab may be reduction in hepcidin, a molecule produced by the liver upon stimulation by IL-6 and that downregulates iron absorption in the gut [128]. Moreover, serum levels of VEGF return to normal in patients treated with tocilizumab [111], and given the importance of angiogenesis in synovial inflammation, this may play a role in the efficacy of the drug.

All therapeutics neutralizing cytokines carry the potential to increase the risk of infection secondary to immunosuppression. In particular, infliximab has been associated with tuberculosis [18]. In this regard, animal models suggest that therapeutics targeting the IL-6 pathway may have an advantage, since in contrast to mice inoculated with *M. tuberculosis* and treated with anti-TNF antibodies, those treated with antibodies to IL-6R survived. This is in keeping with the key role played by TNF in granuloma formation, and the increased risk of tuberculosis with infliximab may be related to reduced IFNγ [129, 130].

## 7 INTERLEUKIN-23/INTERLEUKIN-17 PATHWAY

The discovery of IL-23 at the turn of the millennium has heralded extraordinarily rapid advances in the understanding of tissue-specific autoimmune disease. IL-23 was identified by structure-based searching of the genome for IL-6 cytokine family members and is a heterodimeric cytokine consisting of a p40 subunit, which it shares with IL-12, and a unique p19 subunit [131, 132]. Like IL-12, IL-23 is produced by activated macrophages and dendritic cells, but its main targets are activated rather than naïve T cells [131, 132] as well as myeloid cells [133]. Its receptor consists of IL-12Rβ1, which it shares with IL-12, and a unique component IL-23R [134], which confers specificity to IL-23.

Classical investigation of the IL-12 cytokine pathway in inflammatory arthritis and other autoimmune diseases used genetic or serological targeting of the p40 subunit of IL-12. Indeed anti-p40 antibodies reached clinical trials to test the efficacy of IL-12 blockade before it was discovered that they also can result in neutralization of IL-23. With the discovery of IL-23, it became obvious that the importance attributed to IL-12 with anti-p40 blockade had been greatly overstated Use of mice deficient in the unique subunits of each cytokine, rather than the common p40 subunit, has shown that IL-23, rather than IL-12, is the critical cytokine in CIA [50]. Furthermore, its role as a master regulator of autoimmune inflammation beyond the joint has been demonstrated by its critical position in the control of autoimmunity in the central nervous system (CNS) [133, 135], bowel [136–140], and skin [141, 142].

Traditionally, experiments targeting IL-12p40 led to the paradigm that tissue-specific autoimmune disease was dependent on IL-12-driven Th1 lymphocyte polarization and production of IFNγ. However, many observations, particularly in humans, were not consistent with this model, and in particular the role of IFNγ in autoimmunity was much more complex than the model predicted [143]. Indeed, when administered 24 h before inducing arthritis with adjuvant, IFNγ enhanced arthritis. However, when given after immunization, arthritis was actually suppressed [144]. Daily administration of IFNγ to Lewis rats after induction of adjuvant arthritis resulted in suppression of paw swelling, regression of bone lesions, reduction in splenomegaly, and reduced systemic inflammatory response as measured by ESR [145]. Conversely, loss of IFNγ [146] or its receptor [147] resulted in increased severity

of CIA as well as other tissue-specific autoimmune diseases.

Writing only a few years after the discovery of Th1 and Th2 lymphocyte subsets by Mosmann et al. [148], Jacob's group had already highlighted conflicting reports addressing the importance of IFNγ in autoimmunity and suggested that this might reflect the activity of additional distinct T-cell subsets [144]. While the existence of further subsets had also been predicted in Mosmann and co-workers' seminal paper [148], and suggested following characterization of IL-17 producing human T cells [149], it is only recently that the details of these subsets, the transcriptional master regulators that regulate their production and the cytokines that they produce, has come to light.

Although the predominant action of IL-23 on mouse memory T cells had been appreciated since its discovery [132], a key breakthrough came with the finding that it stimulated memory T cells to produce IL-17 [150]. It is now clear that IL-23 drives autoimmune pathology by stimulation of a unique T-lymphocyte subset now termed $T_h17$ [151] and has a particular role in the maintenance of this subset [131, 152, 153]. In contrast to $T_h1$ cells, which express genes important in cytotoxicity, such as *FasL*, TNF-related apoptosis-inducing ligand (TRAIL), interferon-γ (IFNγ) and granzyme, $T_h17$ cells regulate local tissue inflammation by producing IL-6, TNF, IL-22, and IL-17 [135]. In keeping with the broad expression of its receptor, IL-17 itself acts on multiple cell types to cause the release of a diverse range of pro-inflammatory cytokines [154]. Notably, it induces stromal, epithelial, and endothelial cells and monocytes [154] to express TNF and IL-1β [53] and fibroblasts to secrete IL-6 and IL-8 [155, 156]. It enhances recruitment of neutrophils by inducing secretion of the neutrophil chemokine IL-8 from epithelial and endothelial cells and rheumatoid synovium [154] and stimulates neutrophil production through release of granulocyte colony stimulating factor (G-CSF) [157]. Thus IL-17 emerges as a critical molecule in orchestrating autoimmune inflammation. Its action on cells usually forming compartmental boundaries, such as endothelial or epithelial cells, places it in a prime position to mediate the breakdown of these barriers and stimulate the inflammatory infiltration of joints and other organs. While research on IL-17 has focused predominantly on its pathogenic effects, the beneficial roles played by IL-17 include the ability to respond to serious injury or infection [158] by rapidly mounting a massive inflammatory response through the recruitment of neutrophils.

Raised IL-17 levels have been detected in CIA [50], and adenoviral-mediated overexpression of IL-17 in joints exacerbates CIA, causing increased joint destruction as assessed histologically and radiographically [159]. While this is associated with upregulation of IL-1β, neutralization of IL-1β is without effect. IL-17 also exacerbates streptococcal cell-wall-induced arthritis, converting it into a severe chronic arthritis with increased damage to cartilage, and notably can substitute for the usually obligate role of IL-1 in proteoglycan depletion [160]. Conversely, genetic ablation of IL-17 ameliorates CIA [161], as does neutralization of IL-17 [160, 162, 163], which is associated with reduced inflammation, decreased receptor activator of nuclear factor kappa-B ligand (RANKL) expression, and bone erosion [162]. Mice lacking IL-12p35 have increased $T_h17$ cells and exacerbated CIA associated with reduced IFNγ, whereas mice lacking IL-23p19 are completely resistant to CIA and have raised IFNγ expressing Th1 cells [50]. This not only demonstrates the key role of IL-23 and IL-17 in joint pathology and the reciprocal nature of the Th1 and Th17 pathways but also demonstrates the paradoxical protection from autoimmune inflammation mediated by IFNγ, which is consistent with the historical observations detailed above. The opposing roles of IFNγ and IL-17 extend beyond simply *inflammation* in the joint, since IFNγ itself inhibits osteoclastogenesis and hence bone erosion, whereas $T_h17$ cells are directly osteoclastogenic through expression of IL-17 and trigger bone loss even in the absence of autoimmunity [164]. Furthermore, $T_h17$ cells express RANKL [164] and IL-17 induces expression of RANKL in osteoclastogenesis-supporting cells [165], demonstrating multiple routes by which IL-17 can cause the erosive pathology associated with RA.

The importance of IL-17 in human pathology has been confirmed by human studies that have shown raised levels of IL-17 in synovial fluid, serum, and synovial biopsies of RA patients compared with OA patients [165–168]. Remarkably, some time before the current interest in $T_h17$ cells, immunohistochemistry of synovial biopsies from RA patients demonstrated memory $CD4^+$ T cells ($CD45RO^+$), which co-stained for IL-17 [165], suggesting that $T_h17$ cells are present in the rheumatoid synovium. Joosten et al. have also demonstrated IL-$17^+$ T cells in the synovium [81], and cloning of T cells from the rheumatoid synovium demonstrates the presence of IL-$17^+$ IFN$\gamma^+$ double-positive T cells [149]. It will be very informative to define the identity of T lymphocytes associated with destruction in RA.

Human studies demonstrate multiple aggressive functions of IL-17 in the joint. IL-17 promotes formation of osteoclasts in vitro, as does the culture media of RA synovial tissues [165]. The ability of the latter to stimulate differentiation of osteoclasts is reduced by 80% when IL-17 is neutralized, emphasizing the key role played by IL-17 in osteoclastogenesis. IL-17 also causes increased IL-6 production and collagen

destruction by RA synovial explants, increased bone resorption, and decreased formation by RA bone explants, effects that are exacerbated by the addition of IL-1 [172]. Blocking endogenous IL-17 in these models reduces bone destruction. Of significance, IL-17 simulates a positive feedback loop that may perpetuate autoimmune inflammatory joint disease. Thus RA T cells induce fibroblasts to produce the major inflammatory cytokines TNF, IL-15 and IL-18, which in turn further stimulate the T cells to release IL-17 and IFNγ to further stimulate the fibroblasts [168]. IL-17 then synergies with TNF to cause cartilage destruction [173]. The relevance of these findings is emphasized by the observation that messenger ribonucleic acid (mRNA) levels of IL-1β, TNF, IL-10, and IL-17 are predictive of the rate of progression of joint damage in RA, and that IL-17 and TNF are also synergistic in this model [174]. As previously noted [175], many of these experiments have unfortunately not included measurements of IL-23; however, one report demonstrates raised IL-23p19 in the sera and synovial fluid of RA patients, compared with OA or healthy controls [176]. Since IL-17 was found to induce IL-23p19 expression in fibroblasts [176], this again highlights the effects of positive feedback in Th17 mediated joint inflammation.

Further potential cytokine targets have emerged from studying the control of T cells producing IL-17, and key differences have emerged between murine and human $T_h17$ cells. Whereas, in the mouse, IL-23 is important for IL-17 cell expansion and commitment in keeping with the early observations by Oppmann et al. that IL-23 acts on murine memory cells [132] and those of Aggarwal showing that IL-23 augments IL-17 production from memory but not naïve T cells [150], Th17 cells are produced from murine naïve cells not by the action of IL-23 itself but by transforming growth factor β (TGFβ) and IL-6 [153, 177, 178]. While TGFβ has often been considered an anti-inflammatory cytokine, and is pivotal in polarization of $T_{reg}$ lymphocytes, it is now suggested that in the context of inflammatory stimuli, and thus IL-6 production, T cells may be diverted from a $T_{reg}$ fate into Th17 cells and thus that the two populations have reciprocal developmental pathways. Similarly, while IL-2 is vital for $T_{reg}$ cells, it potently impairs generation of Th17 cells [179], again suggesting dichotomous polarization. Recently, the action of IL-6 has been shown to be mediated by IL-21, which is produced by Th17 cells and acts in an autocrine feedback mechanism to stabilize Th17 polarization [180]. The combination of IL-6 and TGFβ does not polarize *human* $T_h17$ cells, which instead undergo differentiation in response to IL-23 itself in combination with IL-1β [171], in keeping with the original observations of Oppmann and coworkers that IL-23 can act on human naïve T cells [132]. While several papers have confirmed the suppressive effects on TGFβ on $T_h17$ development in humans [181, 182], IL-6 has emerged as a strong stimulator of $T_h17$ cells in the absence of TGFβ [181] and in combination with IL-1β. This raises the question as to whether the success of anti-IL-6R antibodies in RA is contributed to by inhibition of $T_h17$ cell polarization. Very recent experiments have identified key elements of the innate immune system responsible for polarization of Th17 cells, including the intracellular molecule nucleotide oligomerization domain 2 (NOD2) [183] and Toll-like receptors [182]. The field of human $T_h17$ cell biology is developing rapidly, and it is likely that work over the next few years will clarify the conditions under which these cells develop in humans.

A key question is which of the cytokines in this new pathway represent the best therapeutic target for RA, an issue that has not yet been directly addressed in animal models. IL-17 is promising, particularly given the fact that neutralization of this cytokine will directly target the T-cell subset responsible for autoimmune inflammation. This view is supported by the success of therapeutics targeting IL-17 in animal models. Yet, while IL-17 is important, the upstream cytokine IL-23 has additional actions beyond induction of IL-17. Indeed early work concentrated on its ability to directly activate myeloid cells; IL-23 directly induces peritoneal macrophages to upregulate TNF and IL-1β and acts via IFNγ to stimulate expression of a further set of pro-inflammatory molecules [133], and injection of IL-23 into the skin results in what is essentially a wound-healing response [141]. Furthermore, a T-cell-independent model of inflammatory colitis induced with anti-CD40 antibodies in recombinase activating gene (RAG) deficient mice demonstrates that IL-23 is critical for local tissue pathology despite the absence of T cells and, interestingly, shows local production of IL-17 in the colon—most likely by innate immune cells—that is dependent on IL-23 as it is abrogated in p19 and p40 KO mice [138]. Several observations also underline the vital role of IL-23 in the continued operation of $T_h17$ lymphocytes [140]. For example, while $T_h17$ cells can develop in the absence of IL-23 upon infection with the intestinal pathogen *Citrobacter rodentium*, full protection of the host requires IL-23 [178]. Similarly, neutralization of IL-23p19 prevents the inflammatory bowel disease (IBD) induced by transfer for $T_h17$ cells and can also treat established disease. Thus IL-23 plays a key role in the optimal expansion of $T_h17$ cells but has independent pro-inflammatory effects on the innate immune system, thus representing a critical target for therapeutic use. Moreover, in combination with IL-18, IL-23 can induce TCR-independent production of IL-17 from T cells [184], emphasizing the important role therapeutics targeting IL-18 may have in the regulation of this pathway. Cytokines in addition to IL-23 may play impor-

tant roles in maintaining the function of $T_h17$ cells. Indeed it has been noted that IL-1R1 KO mice have a defective Th17 response to immunization, and T cells deficient in IL-1R1 do not produce IL-17 when cultured with IL-23 [152].

It is hoped that targeting the IL-23 pathway will not be accompanied by substantial infective complications. Indeed studies from France have demonstrated that patients with combined defects in the IL-12 and IL-23 pathway due to mutations in the shared p40 ligand or IL-12Rβ1 receptor subunits have susceptibility to only two classes of pathogens—salmonella and mycobacteria, similar to those with mutations in the IFNγ pathway [185, 186]. While p40-deficient mice are susceptible to many pathogens, use of specific IL-12- and IL-23-deficient mice has shown that this is largely due to the defect in the IL-12/IFNγ pathway, with a contribution from IL-23 only being detected in the absence of IL-12. Additionally, infections that appear to require the presence of the IL-23/IL-17 pathway in mice, such as *Klebsiella* [187] and systemic *Candida albicans* [188], are not prevalent in humans with mutations in p40, again providing an encouraging prediction of low infective risk with IL-23 blockade and emphasizing the difference between mouse and human IL-23/Th17 biology.

## 8 OTHER THERAPEUTIC STRATEGIES

While we have focused on cytokine-based therapeutics, multiple other targets exist against which biological agents can be developed and that we have not been able to cover in this review. For example, great success has recently been attained by reducing numbers of B cells with the anti-CD20 agent rituximab [189], promoting an increased appreciation of the role of humoral immunity in RA. This also raises the question of whether the best strategies will target cytokines themselves or their cellular source. However, it is notable that so far other cellular targets have not had promising results [6]. Increased understanding of the signaling cascades inside cells has given rise to additional therapeutic targets, as has increased mechanistic knowledge of the chemokines responsible for the regulation of cellular trafficking in autoimmune inflammation [190, 191]. The critical role of angiogenesis [190] in promoting a rich vascular supply for inflammatory cells and molecules to reach the normally minimally vascular synovium is frequently emphasized; however, to date this process has not been specifically targeted. Furthermore, greater knowledge of osteoimmunology [192, 193] has allowed the key interactions between inflammatory cells and osteoclasts to be understood and has identified critical molecules, such as RANKL, necessary for osteoclast activation, many of which represent promising therapeutic targets.

A theme that emerges is the enormous complexity and multilevel interaction between all of these systems—cytokines, chemokines, co-stimulatory molecule expression, angiogenesis, and osteoclast activation. Thus neutralization of many of the cytokines we have discussed has affected, for example, the expression of co-stimulatory molecules or angiogenesis as well as expression of other cytokines. Clearly, the development of optimal clinical therapeutics must take into account these complex networks of interactions. It may be that certain patients require more than one biological therapeutic, and thus greater understanding of the use of anticytokine reagents in combination is needed. Furthermore, it must be highlighted that the cytokine patterns of very early rheumatoid arthritis are distinct from later cytokine expression profiles [194], emphasising that therapeutic approaches may need to differ depending of the phase of the patient's disease during which treatment is being administered.

Given the success of hematologists in using combinations of cellular markers, cytokine levels and genetic profiles to predict responses to treatment and to clarify prognosis [195–201], it would be rewarding if a greater understanding of cytokine biology by rheumatologists not only lead to the development of further therapeutics but also to algorithms that would predict responses to specific drugs.

Not only are developments in the identification and targeting of cytokines vital, but the detailed pharmacology of the therapeutics themselves is of critical importance. Already it is striking to note that patients not responding to one TNF-neutralizing drug may respond well to another, emphasizing that details of the manner of targeting (by antibody or decoy receptor), and route of administration (subcutaneous or intravenous) is as important as the molecule that is targeted. Additionally, the use of large molecules, such as antibodies and decoy receptors, to target cytokines necessitates parenteral administration. Knowledge of pathways downstream of the relevant receptors may allow development of small-molecule agents that will inhibit the ability of cytokines to trigger cellular responses, with the advantage that these agents could be orally active. While novel methods of neutralizing TNF have included liposomal delivery of small interfering RNA in animal models [202], complete cure of CIA necessitates ongoing administration, making an orally administered drug an attractive option.

The study of cytokine biology has proved to be highly rewarding from a therapeutic perspective. The proof of concept demonstrated by the success of anti-TNF agents, combined with the experimental ease with which cytokines can be investigated and manipulated, has opened the future of rheumatology to exciting new conceptual and therapeutic prospects.

## 1 INTRODUCTION

The advances in the molecular neurosciences during "the decade of the brain" in conjunction with new genomic and proteomic sciences have radically changed the paradigm of central nervous system (CNS) drug design and development. The classical, chemistry-based small-molecule drug discovery has been broadened by the twenty-first century biology-driven paradigm of large-molecule neuropharmaceuticals: peptides, recombinant proteins, monoclonal antibodies, antisense oligonucleotides, and gene therapy [1].

An interdisciplinary approach focusing on the chemistry–biology interface would facilitate a more rapid and efficient discovery process of novel lead compounds for CNS diseases. Moreover, combinatorial chemistry and high-throughput screening techniques, combined with structure-based or ligand-based de novo design algorithms, have resulted in libraries containing hundreds of thousands of drug candidates with diverse chemical bases and have consequently enormously increased the possibility of finding new lead structures. Synthetic chemistry platforms paralleled by high-throughput screening (HTS) serve as decision aids in planning neuropharmaceutical development projects. A computational prediction strategy that classifies the compounds by their high-affinity to the target and adequate biopharmaceutical properties must be incorporated early in the discovery process because it would enable rapid selection of promising new chemical entities and also would save both costs and time. [2, 3].

Despite the progress in the field of neuroproteomics and rational drug design strategies, there is still a high failure rate of the candidates in later stages of projects (over 98% of novel compounds do not cross the blood–brain barrier) and consequently an unsatisfied demand for novel neurotherapeutic and neurodiagnostic medicines. Therefore, CNS drug discovery and CNS drug targeting must be merged early in the CNS drug development process in order to obtain neuropharmaceuticals active in the brain following systemic administration [1, 4].

## 2 NEUROPROTECTION AND CNS DISORDERS

The enormous social and economic impact of CNS disorders is highlighted by the incidence of 80 million cases in the United States and the annual cost exceeding $90 billion per year [1]. For example, the financial cost to society of Alzheimer's disease (AD) is estimated at $20–$40 billion per year in the United States [5].

*Amyotrophic lateral sclerosis (Lou Gehrig's disease, ALS)* is a prototypic age-related neurodegenerative disease, characterized by the progressive and specific loss of motor neurons in the brain and spinal cord, which begins in midadult life (the average age at onset is 55 years), life expectancy after the clinical onset varying between 3 and 5 years [5, 7, 8]. Two clinically indistinguishable forms of ALS have been identified: the sporadic form accounting for 90% of cases and the

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

familial form accounting for 10% of cases. In 10–20% of patients with dominant familial ALS mutations of the superoxide dismutase *SOD1* genes have been detected. Neuronal caspase activation (especially caspase 1, 3, and 9), cytochrome c release, and proapoptotic changes in the *Bcl-2* family have also been revealed in spinal cords of animal models of ALS [7].

Neuropathology of ALS comprises the marked reduction in synaptophysin expression that parallels the severity of the neuronal loss and the aberrant accumulation of neurofilaments in the anterior horns of the spinal cord; degeneration of lower motor neurons from the nuclei of cranial nerves and from the ventral horn of the spinal cord; atrophy of striated muscles; and ubiquitin-labeled skeinlike structures in anterior horn nerve cells. The current pathogenetical hypotheses in ALS neuronal death include complex interaction between altered functions of mitochondria and cytoskeleton, glutamate excitotoxicity, and oxidative stress. To date, no therapeutic approaches have been able to significantly improve the course of the disease and riluzole, the only recognized treatment, prolongs survival by 3 months [5].

*Huntington's disease (HD)* is an autosomal-dominant with complete penetrance neurodegenerative disorder, characterized by selective destruction and gliosis of GABAergic, enkephalin- and substance P-containing medium-size spiny neurons within the caudate nucleus and putamen. The loss of inhibitory innervation to the globus pallidus and substantia nigra pars reticulata leads to hyperactivity of the dopaminergic system. The prevalence of HD is between 5 and 10 per 100,000; its onset usually occurs during the fourth or fifth decade of life and is invariably fatal in 10–20 years after the onset of clinical symptoms. HD is characterized by restless, progressive involuntary choreiform movements with psychiatric and cognitive deterioration and dementia [5, 7].

The disease is caused by a mutation of a gene located on the short arm of chromosome 4 (the mutation responsible for the abnormal expansion of CAG-encoded polyglutamine repeats). It has been suggested that the gene product, huntingtin, might be related to the caspase mechanism of apoptotic cell death. One of the earliest events seems to be transcriptional upregulation of the caspase 1 gene, possibly resulting from nuclear translocation of N-terminal fragments of mutant huntingtin. As the disease progresses, there the caspases 3, 8, and 9 are activated and the caspase-mediated cleavage of huntingtin is triggered with an increased generation of huntingtin fragments and depletion of wild-type huntingtin. The caspase-mediated cascade determines the downregulation of the receptors that bind other important neurotransmitters, leading to extensive neuronal dysfunction [8]. Recent studies provide strong evidence for transcriptional dysregulation mediated by aberrant histone acetyl transferase activity as a mechanism of HD pathogenesis [9].

*Parkinson's disease (PD)* is a progressive degenerative disease whose cardinal features are resting tremor, bradykinesia, rigidity, cognitive impairment, and dementia. PD results from degeneration of pigmented cells in the substantia nigra and dopamine depletion of the nigrostriatal system, as well as perturbations of other neurotransmitter systems [10–12].

Pharmacological neuroprotection is largely substitutive and aims to compensate the loss of dopaminergic neurons. Oral L-DOPA associated with carbidopa as peripheral L-amino-acid aromatic decarboxylase inhibitor, the mainstay of current therapy, ameliorates clinical symptoms for a limited period (5–10 years) but is unable to stop nigral dopaminergic neuron death. Other disadvantages are the adverse reactions such as dyskinesia and dystonia, due to the lack of site-specific delivery, and the impossibility to maintain sustained drug levels in the CNS resulting in unpredictable "on/off" motor fluctuation [2].

During *stroke* or *traumatic brain injury*, neuroprotection fails in the core of the lesion, characterized by severe hypoxia and necrotic cell death. Neuroprotective pharmacological intervention is confined only to neurons belonging to penumbra where moderate hypoxia, energy deprivation, and relatively delayed apoptosis create a defined therapeutic time window opportune to interfere with the apoptotic cascade [13–16].

Neuroprotection in stroke and acute neurodegenerative diseases must be targeted at the periphery of the focal lesions where it is possible to intervene on the *contagious apoptosis phenomenon* ("the kindergarten effect") by the inhibition of apoptotic cascade not only in the dying neuron but also in the neighboring nerve cells affected by diffusible proapoptotic factors [interleukin-1 (IL-1), tumor necrotic factor-α (TNF-α), free radicals] [8].

There is no effective treatment able to stop the progression of chronic CNS diseases. The clinical efficacy of current pharmacological neuroprotective approaches decreases as the neurodegeneration progresses and is also overwhelmed by adverse side effects due to site-specific delivery inability. In order to restore the morphological and functional integrity of the affected neurons, two complementary strategies have been considered. The former, a "neuroprotective strategy," aims to prevent continuous neurodegeneration by neurotrophic factor gene therapy [5, 8]. The latter, a "substitution strategy," is based on replacement of the lost neurons by fetal neural tissue transplantation and is now undergoing testing in clinical trials. For example, in PD, transplantation of genetically engineered dopamine-

secreting or neurotrophins-secreting autologous grafts provides an alternative for long-term symptomatic relief and restoration of neurological function [17].

## 3 CRUCIAL ROLE OF THE BLOOD–BRAIN BARRIER (BBB)

### 3.1 Functional Organization of the BBB

The BBB represents the interface between blood and brain and has a vascular aspect represented by capillary endothelium and collagen basement membrane with embedded microvascular pericytes and a brain aspect constituted by the continuous sheath of astrocyte foot processes. The endothelial cells of brain capillaries are linked by complex intercellular tight junctions, without fenestrations or pinocytotic vesicles and form together with the thin pericytes layer and astrocyte foot processes the functional neurovascular unit [18, 19].

The BBB is a physical, metabolic, and pharmacological barrier. The BBB is selectively permeable, playing an important role in regulating the ions influx and efflux, nutrient uptake, and metabolite and xenobiotic clearance between plasma and brain parenchyma. The tight junctions of brain capillary endothelial cells are missing in some areas, for example, circumventricular organs, area postrema, median eminence of the hypothalamus, pineal gland, and the choroid plexuses, where the BBB is considered to be "interrupted," allowing the passage of proteins and small organic molecules [7].

### 3.2 Prediction of Drug Permeability through the BBB

Prediction of BBB permeation has become an essential issue in project development in the neuropharmaceutical industry and must be assessed early, as well as at different phases in the discovery process, in order to achieve a high rate of success and time and cost benefits. BBB penetration prediction in industry is often based on different available models (in vitro, in silico, in vivo) applied in parallel [20]. The animal experimental determination of blood–brain partitioning with radiolabeled and nonradiolabeled compounds is characterized by the highest level of predictability, but also by the highest cost and time requirements, and lowest throughput; various in vitro models of the BBB require interlaboratory validation [20, 21].

Consequently, in silico approaches, mainly based on the correlation between physicochemical properties (solubility, lipophilicity, molecular size, hydrogen-bonding capacity, charge, polar surface area, and solvent-free energies) and the ability of molecules to cross the BBB, either by transcellular passive diffusion and active transport (e.g., receptor-mediated or carrier-mediated transcytosis) have been developed [21, 22]. Rational neuroactive drug design involves computational approaches for prediction of drug permeability through the BBB [23, 24]. Molecular descriptors, together with Bayesian-regularized neural nets, were employed to model the partitioning of a diverse range of drugs and other small molecules across the BBB [25].

### 3.3 BBB Genomics and Proteomics

The application of genomic and functional proteomic methods in BBB research has revealed that, compared to brain or peripheral tissues, its unique molecular characteristics are derived from the brain capillaries genes' differential expression and specific protein profile expression. The selectively expressed genes mediate both BBB functions and the complex involvement of the BBB in neuropathology.

These new methodologies, considered the most powerful ever applied to brain drug development, aim to identify novel, selectively expressed, endogenous transporters as new targets for innovative drug delivery through the BBB in vivo [1, 4, 18, 26].

### 3.4 Strategies for Brain Drug Targeting

The invasive neurosurgical-based strategies either deliver drug *behind* the BBB (intracerebroventricular infusion or intracerebral implants) or physically *disrupt* the BBB following the intracarotid infusion of noxious agents [1].

Strategies for the *noninvasive BBB drug targeting* focus on the endogenous BBB transport systems [receptor-mediated transcytosis (RMT) or carrier-mediated transport across the brain capillary endothelium), which are revealed by BBB genomics and proteomics programs and allow drugs to be transported *through the BBB*.

*Chimeric peptide technology* involves the conjugation of the neuropharmaceutical agents (small molecules or peptidomimetic compounds) to a brain-targeting vector that binds with high affinity and specificity to a BBB-expressed transport system and triggers the transcytosis through the BBB in vivo. The cited brain drug-targeting *vectors* include monoclonal antibodies or "endocytosing MAb" [human insulin receptor (HIR) monoclonal antibody (HIR MAb) or the transferrin receptor (TfR MAb)], endogenous peptides, or plasma proteins (ligands for the RMT or absorbtive-mediated systems), highly cationized proteins (cationized humanized MAb) [1, 27]. The *linker strategy* (chemical conjugates, genetically engineered fusion proteins, avidin-biotin, or

pegylated immunoliposome technology) must be chosen to assure the bifunctionality of drug–vector conjugate and to optimize its plasma pharmacokinetics in order to improve its brain uptake [1].

## 4 DESIGN OF ANTISENSE NEUROPHARMACEUTICALS

Antisense oligonucleotides (antisense OGN) are short, monocatenar, synthetic sequences of chemically modified nucleic acids, which specifically hybridize, according to the base-pairing rules (adenine–tymine/uracil, guanine–cytosine), with the complementary nucleotide sequences from target deoxyribonucleic acid (DNA) or target ribonucleic acid (RNA), thus blocking the protein synthesis encoded by these targets in certain cells/tissues. The antisense mechanisms of action include activation of ribonuclease H (RNase H, the enzyme that cleaves the messenger RNA (mRNA) strand from the mRNA/antisense OGN hybrid), translation arrest, inhibition of polyadenilation or 5′-capping, splicing inhibition, and target mRNA degradation due to intrinsic catalytic properties of the ribozymes [28].

There are several chemical classes with distinct antisense properties, their medicinal chemistry being described in Crooke [29] and Gualtieri [30]. Peptide nucleic acids (PNA), consisting of repetitive *N*-aminoethylglycine units, represent *very attractive lead compounds* for the development of antisense drugs because of their (1) neutral, achiralic, hydrophilic, and low-molecular-weight structure; (2) intense hybridization properties; (3) high chemical and biological stability; (4) negligible interactions with proteins and thus low toxic effects; (5) ease of synthesis; (6) absence of neurotoxicity; and (7) design as neurodiagnostic and neurotherapeutic agents by conjugation with BBB delivery systems.

The antisense oligonucleotides as neuropharmaceuticals have the following *advantages* over the classical medicines: (1) remarkable selectivity because antisense OGN discriminate between closely related proteins derived from homologous genes, polymorphic alleles, or alternative splicing products; (2) highly specific regional targeting in the brain; (3) facile design and shorter period required to develop an antisense drug due to powerful in vitro and in vivo screening methods; (4) the possibility to select the most susceptible situs of the targeted mRNA for antisense hybridization; (5) the opportunity to choose the most specific, selective, and stable antisense oligonucleotide from a wide range of chemical modifications; and (6) simple solid synthesis (phosphoramidite method) at low cost [28, 30].

The *antisense neurotherapeutic candidates* might be indicated in neurodegenerative disorders, brain viral disease, and cerebral tumors. For instance, in HD, the molecular target for antisense strategy is either huntingtin or glyceraldehyd-phosphate-3-dehydrogenase (GAPDH) mRNA; in cerebral acquired immure deficiency syndrome (AIDS), human immunodeficiency virus (HIV) mRNA; in malignant gliomas, antisense OGN are directed against aberrant transcripts responsible for the uncontrolled growth and proliferation. The neuroprotective role of the antisense OGN anti-NMDA-R1 receptor transcript was demonstrated in rat models of cerebral ischemia [29].

In contrast to classical AD therapy, very low doses of antisense OGN targeted to specific acetylcholinesterase (AChE) isoform transcripts appear to be the only solution to block de novo synthesis of AChE protein, thereby inhibiting both its catalytic and noncatalytic activities. In familial AD, phosphorothioate antisense directed to presenilin-1 mRNA proved to be a neuroprotective activity against NMDA-induced neuronal cell death [28, 31–33].

The antisense oligonucleotide AS3 specific to AChE, in trauma-sensitive AChE transgenic mice, minimized mortality, facilitated neurological recovery, and protected CA3 hippocampal neurons, suggesting its possible role in the treatment of acute head trauma. AS3, delivered in nanomolar quantities by surgically implanted cannulae to the cerebrospinal fluid (CSF) of cognitively impaired transgenic mice, has shown promising results [28].

Antisense radiopharmaceuticals as *neurodiagnostic tools* are useful for direct and early detection of the exact moment of expression of any pathologic gene in vivo [1].

Antisense oligonucleotides have been proved as important *tools in validating* different isoforms of CNS proteins as *potential targets* for therapeutic intervention, such as β-secretase and caspase-2 in AD [34], 5-$HT_{2A}$ receptors, and corticotropin-releasing factor (CRF2) receptors in anxiety and depression, galanin (GAL1) receptors in galanin antinociceptive effects, neuropeptide Y role in food intake regulation, adenosine triphosphate (ATP)-dependent A-type potassium channel Kv1.4 in the long-term potentiation and spatial memory, the opioid receptors mu, delta, kappa characterization, and nNOS-1 and nNOS-2 role on morphine analgesia [28].

## 5 NEUROTROPHIC FACTORS—A PROMISING THERAPEUTIC STRATEGY

### 5.1 Classical Neurotrophic Factors

Neurotrophic factors belong to neuronal intrinsic homeostasy. They are proteins that act on neurotrophin

receptors and regulate the neuronal survival/death ratio by stimulating neuroblastic growth and differentiation, axonal sprouting to final anatomical targets, hierarchical distribution of synapses on somatodendritic surfaces, dendritic spines proliferation, synaptic plasticity, and normal brain chemical architecture.

Different neurotrophic factors have distinct roles in modulating the function of a neuron or specific neuronal populations. In the living brain, neurotrophic factors are associated in various combinations that act synergistically to promote neuronal survival and regeneration in CNS diseases.

The neurotrophin receptors are classified as (a) the *nonspecific* low-affinity p75 receptor, able to bind all neurotrophins and modulate their interactions with trk receptors and (b) *the family of tyrosine kinase-linked (trk) receptors*, which bind specific neurotrophins.

The neurotrophic factors are divided into (a) *the classic neurotrophin family* including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), neurotrophin-4/5 (NT-4/5), and the nonmammalian growth factors neurotrophin-6 (NT-6) and neurotrophin-7 (NT-7); (b) *the cytokine family*, consisting of leukemia inhibitory factor (LIF or cholinergic differentiation factor), ciliary neurotrophic factor (CNTF) and cardiotrophin-1; (c) *the fibroblast growth factors family*, with FGF-1 and FGF-2 (also known as acidic FGF and basic FGF); (d) *insulin and insulin-like growth factors* (IGF-I and IGF-II); (e) *the transforming growth factor-β (TGF-β) superfamily* containing: glial cell-line-derived neurotrophic factor (GDNF), neurturin, persephin, and the bone morphogenic proteins (BMPs); (f) *the epidermal growth factor family* including epidermal growth factor (EGF), transforming growth factor-α (TGF-α), neuregulins, and NTAK (Neural- and Thymus-derived Activator for ErbB Kinases); and (g) *additional molecules with growth-promoting activities*: and hepatocyte growth factor (HGF), immunophilins, platelet-derived growth factor (PDGF), interleukins, heparin-binding neurotrophic factors (pleiotrophin) [5].

The mature forms of neurotrophins are released by proteolytic cleavage of their precursor forms, proneurotrophins, which might have distinct and sometimes contrasting effects in comparison with the mature neurotrophins on neuronal survival and degeneration and on regulating synaptic plasticity in neuropathological conditions [35, 36].

The success of exogenously neurotrophic factors as neuroprotective and regenerative therapy of neurological disorders is highly dependent on the following aspects: bioavailability after various routes of delivery, developing effective brain-targeting strategies across the BBB, and targeted and safe delivery restricted to specific neuronal populations.

The neurotrophic factors may be delivered by gene therapy to precise brain neuronal population targets, in a potentially safe and long-lasting manner. The in vivo gene therapy approach is based on viral-derived vectors able to directly insert the desired neurotrophic factor gene into targeted brain cell populations. Site-specific transplants of ex vivo genetically modified single cell or small clusters of cells (autologous host cells or xenogeneic grafts from different species) express and secrete human neurotrophins. The polymer-encapsulated genetically engineered cell implants provide the following advantages: characterization (e.g., parameters like neurotrophic factor secretion and stability, homogeneity, and reproducibility) and amplification to generate working cell storage banks, as well as constant delivery to the CNS; prevention of graft rejection and alleviation of the necessity of pharmacological chronic immunosuppression of the host; and the possibility of rapidly retrieving it in the case of undesired side effects [5].

The neurotrophic factor strategy has been validated in small and large animal models of PD, HD, ALS, and AD, using regionally restricted transplants of encapsulated genetically modified cells to secrete diverse neurotrophins. However, some issues remain to be solved in the future: new optimal methods and site of gene delivery, number of neurotrophins-secreting grafts in the brain, the stability and the duration of gene expression achievement, the regulation of gene expression, the duration of neuroprotection after transgene expression ceases, the feasibility of repeating the grafting procedure in the case of downregulation of gene expression, and better methods of testing (innovative neuroimaging techniques) on genetic models of neurodegenerative diseases [5, 37].

Delivery of the neurotrophic growth factors across the BBB, after their peripheral administration, might also be achieved by chimeric peptide technology [1].

Neurotrophic factor therapy is particularly relevant in HD because it may be applied before the onset of striatal neurodegeneration to virtually all individuals of genetically identified families. NGF is the first successful therapeutic undertaking for early phases of AD and HD and is now in a phase III of clinical trial for diabetic neuropathy. BDNF is subject to clinical trials for ALS, preventing the degeneration of basal forebrain cholinergic and GABAergic neurons, and also of the brain stem neurons after axotomy in spinal cord injury models [5].

In the early stages, PD also benefits from dopaminergic growth factor therapy. GDNF is undergoing clinical trials for PD, thanks to its proven remarkable and long-lasting functional stimulatory effects, being the most potent and the most selective neurotrophin on nigral dopaminergic neurons [5]. NT-3 is undergoing clinical trials in neuropathy, spinal cord injury with motor

deficits, and demyelinating conditions. In vivo FGF-1 reduces the neuronal loss after hippocampal ischemia, promotes axonal growth after spinal cord injury, and has entered clinical trials for stroke.

Experimental and clinical data have demonstrated the additive and, in some cases, synergistic neurotrophic effects of combined neurotrophin administration. For instance, BNDF in conjunction with CNTF, or cardiotrophin-1 (CT-1) associated with GDNF, have shown a synergistic neuroprotective effect in mouse models or clinical trials for ALS [5].

### 5.2 Small-Molecule Neurotrophin Mimetics

Design and development of synthetic, small-molecule, neurotrophin mimetics (neurotrophin receptor agonists, partial agonists, inverse agonists or antagonists, modulators of neurotrophin-related signal transduction) that preserve the putative active sites of their larger parent factors and are endowed with favorable profiles of stability, BBB penetration, and targeted biological actions would be useful therapeutic candidates for neurological disorders [38].

Small-molecule TGF-β mimetics might be developed into candidates for the treatment of neurodegeneration because TGF-β is an organizer of the brain's response to injury and is known to be neuroprotective, reducing the accumulation of Aβ peptide [39, 40].

ADNF-9 and nucleosome assembly protein (NAP) are neurotrophic short peptide derivatives of the activity-dependent neuroprotective protein (ADNP) and activity-dependent neurotrophic factor (ADNF) that promote neurite outgrowth, NAP being currently in clinical trials [41, 42].

Pan-neurotrophins and neurotrophic factor "fusion" proteins are synthetic peptides that contain active sites of at least two neurotrophic factors within a single molecule and prove additive neurotrophic properties. For example, pan-neurotrophin-1 is a fusion of NGF, BDNF, and NT-3 active sites. Pan-neurotrophins are designed as potential therapeutic strategy for neurological disorders characterized by the degeneration of multiple types of neurons, including stroke, trauma, and AD [5].

## 6 NEUROTRANSMITTER SYSTEMS AS THERAPEUTIC TARGETS

### 6.1 Chemical Central Synapse

Chemical transmission is the most important mechanism by which the neurons communicate with one another. Morphologically, the interneuronal contact called synapse is formed by the presynaptic membrane (axonal termination), the synaptic cleft, and the postsynaptic membrane (somatodendritic) encapsulated by glial cells. Chemical transmission of information requires successively: (1) the presence of the neurotransmitter in the presynaptic terminal stored in secretory vesicles, (2) quantal release in the synaptic cleft by exocytosis, (3) the presence of specific receptors on the postsynaptic membrane, and (4) the mechanism of neurotransmitter inactivation. The iontophoretic application of neurotransmitter on postsynaptic receptors should mimic the electrical stimulation of presynaptic terminal.

*The life cycle of a neurotransmitter (Fig. 1)* is a sequential process that starts with *precursor uptake* into the neuron from the glial cells. *Enzymatic processing* of precursor and *neurotransmitter synthesis* take place in the endosomes in the presence of mitochondria. By *budding*, the endosome gives rise to the neurotransmitter vesicle that is progressively *translocated* to the active zone of the presynaptic membrane. Here, in the presence of $Ca^{2+}$, selected specific proteins (synapsin, syntaxin, synaptobrevin) realize the attachment (*docking* and *priming*) and the *fusion* of the synaptic vesicle to the active zone, the opening of the vesicle and neurotransmitter release in the synaptic cleft (*exocytosis*).

**Figure 1** Potential targets of neuroprotective strategies (diagram of a chemical central synapse): T1 = precursor inactivation, T2 = enzymatic synthese inhibition, T3 = storage interferation, T4 = release blocking, T5 = intrasynaptic cleft inactivation, T6 = postsynaptic receptor agonist/antagonist interaction, T7 = reuptake (vesicular/transporter) inhibition, T8 = autoreceptor interaction (modulatory), T9 = catabolism inhibition, END = endosome, ENZ = enzyme, P = precursor, PSR = postsynaptic receptor, AR = autoreceptor, T = transportor.

The botulinic toxins are able to disrupt this process between priming and fusion.

In the synaptic cleft the neurotransmitter interacts with the receptors of the postsynaptic membrane, directly coupled with ion channels or with receptors that act through second messengers as G-proteins. In the presynaptic membrane there are neurotransmitter autoreceptors that modulate exocytosis or neurotransmitter reuptake.

From the synaptic cleft the released neurotransmitter is inactivated by *enzymatic degradation*, *reuptake* into presynaptic terminal by endocytosis, by means of a protein transporter coupled with a $Na^+$ channel or by uptake in the glial cells. The reuptaken neurotransmitter is recycled or metabolized by specific enzymes.

*The neurotransmitters* may be classified as excitatory or inhibitory, based on receptor response, but often the quality of response depends upon receptor specialization.

*The neuromodulators* are compounds with both neuronal and nonneuronal origin that act hormone-like and influence the synaptic events, reducing, enhancing, or prolonging the action of neurotransmitters.

The human CNS has two kinds of neurons:

*Long axon Golgi 1* are relay neurons and receive on the somatodendritic membrane more than 90,000 synaptic contacts of which the excitatory ones are located on the peripheral, spiny part of the dendritic tree, while the inhibitory ones on the basal, smooth dendrites and soma. The modulatory synapses are situated presynaptically on the axonal hillock or terminal bouton. The long axons of Golgi 1 neurons project in various brain regions and release a dominant, usually excitatory neurotransmitter in the innervated territory. The therapeutic interference of the neurotransmitter system will be expected to have localized effects related to the territory's function.

*The short axon Golgi 2* are intrarelay interneurons organized as local microcircuits whose terminals secrete inhibitory neurotransmitters. Their therapeutic interference will be expected to have rather generalized diffuse effects. The most important classes of neurotransmitters as targets of neuroprotective strategies will be discussed below.

### 6.2 Serotonin (5-Hydroxytryptamine)

The 5-hydroxytryptamine (5-HT) has been known since the mid-nineteenth century primarily as a cause of hypertension. After its isolation within the CNS, extensive studies demonstrated that the serotoninergic neurons are located in the raphe nuclei of the brain stem reticular formation. According to Dahlstrőm and Fuxe, they are classified into caudal medullary groups (B1–B3), which project into the spinal cord, and pontine and mesencephalic groups (B4–B9), which practically innervate the whole forebrain [6]. Subsequent to these connections, serotonin is involved in every type of behavior, including eating and sleep, in circadian rhythm regulation, neuroendocrine function, and pain perception [7].

Due to the serotonin indolalkyl amine structure and its resemblance to the psychedelic drug lysergic acid diethylamide (LSD), the abnormalities of serotonin synthesis were thought to be involved in various forms of psychic disorders, emesis, migraines, and sexual, sleep, eating, and stress disorders.

Acording to Figure 1, the life cycle of serotonin may be pharmacologically interferred with as follows [2, 7, 43–53]

***T1.*** Diet without tryptophan.

***T2.*** The synthetic pathway of serotonin has two stages: In the first stage the precursor tryptophan is converted to 5-hydroxytryptophan by tryptophan hydroxylase, and in the second, 5-hydroxytryptophan is decarboxylated to form serotonin. During the first stage of synthesis, tryptophan hydroxylase is inhibited by *p*-chlorophenylalanine and α-propyldopacetamide.

***T3.*** The uptake and storage into synaptic vesicles is strongly inhibited, with severe serotonin depletion, by reserpine and tetrabenazine.

***T4.*** The release of serotonin into the synaptic cleft is indirectly inhibited by LSD, which decreases the firing rate of serotoninergic neurons. Until today, there are no therapeutic candidates to interfere with serotonin release.

***T6.*** At least 18 serotonin receptor subtypes are known nowadays. Based on their coupling to second messengers and amino acid sequence homology, they may be divided into: $5\text{-HT}_{1\ (1A,\ 1B,\ 1D,\ 1E,\ 1F)}$, $5\text{-HT}_{2\ (2A,\ 2B,\ 2C)}$, $5\text{-HT}_3$, $5\text{-HT}_4$, $5\text{-HT}_{5(5A,\ 5B)}$, $5\text{-HT}_6$, $5\text{-HT}_7$ families. The opportunities of their pharmacological interference as well as the effector pathways are presented in Table 1.

***T7.*** The presynaptic autoreceptors $5\text{-HT}_{1A}$ (agonist buspirone) are located on the somatodendritic membrane and the $5\text{-HT}_{1B,1D}$ (agonist sumatriptan) on the terminal bouton membrane.

***T8.*** The reuptake into the presynaptical terminal seems to be the main way of serotonin inactivation in the synaptic cleft. The process is inhibited by tricyclic antidepressants (TCA) and selective serotonin reuptake inhibitors (SSRI).

**TABLE 1 Ligands of Serotonin Receptors**

| 5-HT Receptor Subtype | Effector | Agonist | Antagonist |
|---|---|---|---|
| 1A | cAMP, $K^+$channel | 8-OH-DPAT, ipsapirone, piclozotan<br>5-CAT | SDZ 216-525, WAY-100135, spiperone, S(2)-pindolol |
| 1B | cAMP | CP-93,129<br>5-CAT | Isamoltane |
| 1D | cAMP | Sumatriptan, 5-CAT<br>5-(nonyloxy)tryptamine | Isamoltane<br>GR 127935 |
| 1E | cAMP | — | — |
| 1F | cAMP | — | — |
| 2A | $IP_3$/DAG | α-Methyl-5-HT<br>DOI, DOB | Ketanserin, ritanserin, spiperone, LY-53857<br>MDL 100,907 |
| 2B | $IP_3$/DAG | α-Methyl-5-HT, DOI, MK212 | SB 200646A, LY-53857 ketanserin |
| 2C | $IP_3$/DAG | α-Methyl-5-HT, MK212, DOB | SB 200646A, meuslergine, LY-53857, ketanserin, spiperone, metergoline |
| 3 | Cation channel | 2-Methyl-5-HT, *m*-CPBG | Tropisetron, ondansetron, granisetron, zacopride |
| 4 | cAMP | 5-Methoxytryptamine, SB 205149, BIMU8, SC-53116 | GR113808<br>RS 23597-190 |
| 6 | AC | 5-CAT, LSD | Lisuride, clozapine |
| 7 | AC | LSD | Clozapine, amitryptiline |

***T9.*** Serotonin is catabolized by monoamine oxidase (MAO), which is inhibited by MAO inhibitors (MAOIs).

In conclusion, serotonin neurons and receptors are potential targets for a wide class of compounds expected to have antidepressant, anxiolytic, antipsychotic, and antiemetic properties.

### 6.3 Acetylcholine

In 1907, Hunt proposed acetylcholine (ACh) as a mediator of intercellular signaling, in 1914 Dale evidenced its parasympathomimetic action, and Loewi (1921) in his famous "dream experience" demonstrated ACh liberation at nerve terminals after vagal stimulation. After these early discoveries, cholinergic neurons were found in numerous regions of both peripheral (PNS) and central nervous systems (CNS). The cholinergic brain is built up of cholinergic cell groups (Ch1–Ch6) and cholinergic pathways [7, 54].

The Ch1–Ch3 neurons are located in the rostral basal forebrain (medial septal nucleus, nucleus of the diagonal band of Broca, and preoptic area) and project to the hippocampus, the amygdalae, the olfactory bulb, and the limbic cortex. The Ch4 cell group is located in the caudal part of basal forebrain (nucleus basalis Meynert, nucleus ansae reticularis, and substantia innominata) and project to the entire neocortex (pyramidal neurons of layer 5). The Ch5 and Ch6 cell groups are located in the pontomesencephalic region (pedunculopontine and dorsolateral tegmental nuclei) and project to the tectum, thalamus, striatum, substantia nigra, locus coeruleus, and reticular formation. ACh is also synthesized in spinal and cranial nerves motoneurons, transported along the axons, and released at the level of neuromuscular junctions of the skeletal muscles [54].

The ACh is involved in the regulation of biorhythms, of aggressive and sexual behavior, of sleep and arousal, as the neurotransmitter of ascending reticular activating system, as well as in learning, attention, memory, and other cognitive processes that progressively deteriorate in AD.

The life cycle of ACh may be pharmacologically interferred as follows [2, 7, 44, 47, 52, 55–57]:

***T2.*** Styryl pyridine derivatives block the ACh synthesis from acetylCoA and choline.

***T3.*** ACh storage into synaptic vesicles is blocked by AH5183 (vesamicol).

***T4.*** Release is blocked by $Mg^{2+}$, botulinum toxin, cytochalasin B, and is promoted by $La^{3+}$ and β-bungarotoxin.

***T5.*** In the synaptic cleft ACh may be inactivated by stimulation of acetylcholinesterases reactivators. The acetylcholinesterase is inhibited by physostigmine (reversible), by DFP (irreversible), or by donepezil-tacrine hybrid-related derivatives.

***T6.*** The ACh receptors, classically divided into muscarinic and nicotinic, may be classified after resolution of receptor subtypes with chemically synthesized agonist and antagonists. Selective agonists and antagonists of both nicotinic

**TABLE 2 Agonists and Antagonists of ACh Receptor**

| ACh Receptor Subtype | Alcaloid Response | Agonist | Antagonist |
|---|---|---|---|
| Muscular $(\alpha1)_2\beta\varepsilon\delta$, $(\alpha1)_2\beta\gamma\delta$ | Nicotinic | Acetylcholine, nicotine, phenyltrimethyl ammonium, methylcarbamylcholine, dimethylphenylpiperazinium, cytisine, methylisoarecolone | *d*-Tubocurarine, elapid α-toxins, lophotoxin, dihydro-bethaerythroidine, α-bungarotoxin, conotoxin MI |
| Neuronal (α2-α9, β2-β5) | Nicotinic | Acetylcholine, nicotine, methylcarbamylcholine, dimethylphenylpiperazinium, cytisine, methylisoarecolone | *d*-Tubocurarine, trimethaphan, bungarotoxin, lophotoxin, dihydro-bethaerythroidine, κ-bungarotoxin neosurugatoxin |
| $m_1$-$M_1$ | Muscarinic | Acetylcholine, muscarine, pilocarpine, oxotremorine, McN-$A_{343}$ | Atropine, propylbenzilylcholine mustard, quinuclidinyl benzilate, pirenzepine, telezepine, 4-DAMP |
| $m_2$-$M_2$ | Muscarinic | Acetylcholine, muscarine, pilocarpine, oxotremorine, bethanechol | Atropine, propylbenzilylcholine mustard, quinuclidinyl benzilate, methoctramine, gallamine himbacine, AF-DX-116 |
| $m_3$-$M_3$ | Muscarinic | Acetylcholine, muscarine, pilocarpine, oxotremorine, L-689,660 | Atropine, propylbenzilylcholine mustard, quinuclidinyl benzilate, hexahydroxiladifenidol *p*-fluorohexahydroxiladifenidol, 4-DAMP |
| $m_4$-$M_4$ | Muscarinic | Acetylcholine, muscarine, pilocarpine, oxotremorine, McN-$A_{343}$ | Atropine, propylbenzilylcholine mustard, quinuclidinyl benzilate, himbacine, tropicamid, 4-DAMP |
| $m_5$-$M_5$ | Muscarinic | Acetylcholine, muscarine, pilocarpine, oxotremorine | Atropine, propylbenzilylcholine mustard, quinuclidinyl benzilate, 4-DAMP |

and muscarinic receptors are shown in the Table 2.

***T8.*** Choline competitive reuptake is blocked by hemicholinium and troxypirrolinium tosylate.

### 6.4 Inhibitory and Excitatory Amino Acids

***γ-Aminobutyric Acid (GABA)*** GABA is the dominant inhibitory neurotransmitter in the CNS. The GABAergic cell groups are located in various regions of the brain such as the cerebral cortex, hippocampus, striatum, substantia nigra, cerebellar cortex, and spinal cord. The neurons within these areas form long GABAergic pathways (cerebellar Purkinje cells output to deep nuclei and lateral vestibular nucleus and the striatonigral connections) or local microcircuits and realize both post- and presynaptic inhibition.

GABA plays an important role in various physiological and behavioral mechanisms, including locomotory activity, thermoregulation, cardiovascular activity, pain perception, feeding, aggressive and sexual behavior, and is involved in the pathogenesis of epilepsy, tardive dyskinesias, schizophrenia, PD and HD, alcoholism, sleep disorders, and senile dementia [7, 54].

The life cycle of GABA features some attractive targets for therapeutic interference [2, 47, 52, 58–60].

***T2.*** GABA is synthesized from glutamate in a single step, catalyzed by glutamate acid decarboxylase (GAD), and is catabolyzed by the action of GABA aminotransferase (GABA-T) and succinic semialdehyde dehydrogenase (SSADH). This closed-loop process, called GABA shunt, has a double goal, to produce and to conserve the neurotransmitter. Enzymatic synthesis of GABA is inhibited by different hydrazines, but L-glutamate hydrazide and allylglycine seems to inhibit selectively the GAD.

***T4.*** The release of GABA into the synaptic cleft is a calcium-dependent process, but the information concerning selective inhibition of GABA release is still missing.

***T6.*** In mammalian CNS three main subtypes of receptors ($GABA_A$, $GABA_B$, $GABA_C$) have been identified [60–64]. The $GABA_A$ receptors are ligand-gated $Cl^-$ channels that mediate fast inhibitory postsynaptic potentials (IPSPs) in the postsynaptic neuron. The glycoprotein of this receptor is made up of at least three subunits, α, β, and γ, each of them with three to six isoforms. The receptor complex exhibits a GABA binding site that mediates the effects of neurotransmitter agonists and antagonists, and four other binding sites for benzodiazepines, barbiturates, picrotoxine, and neurosteroids. The $GABA_B$ receptors are G-protein-coupled receptors, which are present also in the presynaptical membrane

**TABLE 3 Ligands for Different GABA Receptors Subtypes**

| GABA Receptors Subtype | Agonists | Antagonists | Modulators |
|---|---|---|---|
| $GABA_A$ | GABA, muscimol, isoguvacine | Bicuculline, GABAzine, picrotoxin, TBPS | Benzodiazepines, barbiturates, neurosteroids |
| $GABA_B$ | GABA, baclofen | Phaclophen, 2-hydroxysaclofen, CGP-36742, 3-APPA | — |
| $GABA_C$ | CACA, GABA, muscimol | — | — |

where they inhibit the neurotransmitter release. The $GABA_C$ receptors are also associated to the $Cl^-$ channel, but they show no modulation by benzodiazepines or barbiturates (Table 3).

***T7.*** Presynaptic autoreceptors are probably involved in the regulation of GABA release.

***T8.*** From the synaptic cleft GABA is actively taken up into presynaptic terminals by the sodium-dependent mechanism, which is inhibited by some compounds such as 4-methyl-GABA, 2-hydroxi-GABA, tiagabine, and *N*-methyl-*exo*-THPO [44, 47].

**T9.** The reuptaken GABA is catabolyzed by mitochondrial GABA-T, and this mechanism is inhibited by gabacuculline, nipeconic acid, amino-oxyacetic acid, and acetylenic GABA.

***Glycine*** Glycine is the simplest amino acid that is present in all tissues, participates in different metabolic pathways, and is found especially in the spinal cord and hindbrain where it acts as specific neurotransmitter of Renshaw cells mediating recurrent inhibition. In the brain, glycine is synthesized from serine by the action of serine hydroxymethyltransferase and is released into the synaptic cleft by a calcium-dependent mechanism [44].

The glycine receptors, made up of two subunits, α ($\alpha_1$–$\alpha_4$) and β, are inhibitory ligand-gated $Cl^-$ channels that produce fast IPSPs in the postsynaptic neuron. The major antagonist of the glycine receptor is strychnine, which produces global excitation and convulsant effects. The role of glycine in sensorimotor functions and behavior is confirmed by its involvement in the "startle disease," an inherited disorder characterized by sudden muscular rigidity as a response to an unexpected stimulus (loud noise). Although it is an inhibitory neurotransmitter, glycine also participates as cofactor in the activation of NMDA excitatory receptors [7, 54, 65].

***Glutamate and Aspartate*** Glutamic and aspartic acids act as neurotransmitters in an ionized form called glutamate and aspartate. They have high brain concentration and potent excitatory effects on postsynaptic neurons. Glutamate is a ubiquitous neurotransmitter of the long descending pathways of the motor system, of the limbic projection, including the circuit of Papez and of the parallel fibers of the cerebellar cortex. Aspartate was found as a neurotransmitter of the climbing olivo-cerebellar fibers and of some cortical and hippocampal connection [7, 54].

Glutamate is a nonessential amino acid that does not cross the BBB. Therefore, it is synthesized in the neurons starting from glucose, by transamination of α-oxoglutarate acid and in the glial cells from glutamine by enzymatic action of glutaminase within mitochondria. Glutamate is taken up and stored into synaptic vesicles through $Mg^{2+}$/ATP-dependent mechanism and is released by exocytosis [44].

On the postsynaptic membrane there are the NMDA, AMPA, and kainate ionotropic receptors and G-protein-coupled metabotropic receptors. Activation of NMDA receptors gives rise to slow excitatory postsynaptic potentials (EPSPs) and stimulates some $Ca^{2+}$-dependent enzymes, such as calcium/calmodulin-dependent protein kinase II (CaM-KII), protein kinase C (PKC), phospholipase $A_2$, and nitric oxide synthase (NOS). AMPA and kainate receptors mediate fast EPSPs in the postsynaptic neuron [66, 67]. The metabotropic receptors are classified into three groups based on second-messenger coupling and pharmacological properties and are located on both presynaptic and postsynaptic membranes (Table 4) [65, 68–72].

The rapid removal of glutamate from the synaptic cleft serves both to interrupt the excitatory signal and to prevent the excitotoxic damage. It is taken up into the presynaptical terminal by a specific neuronal $Na^+$-dependent and enantioselective transporter and into glial cells by an other two different glutamate transporters.

*Glutamate Receptors and LTP* NMDA, AMPA, and metabotropic receptors play an important role in the synaptic response enhancement called long-term potentiation (LTP). It was demonstrated that LTP involves increased presynaptic glutamate release and also an increased sensitivity of the postsynaptic membrane. These processes are dependent on the activity of some $Ca^{2+}$-dependent enzymes (Ca M-KII, PKC) and require

**TABLE 4 Excitatory Amino Acid Receptor Ligands**

| Receptor | | Agonist | | Antagonist | |
|---|---|---|---|---|---|
| | | RSSA[a] | RSA[b] | Rssa[c] | Rsa[d] |

the retrograde second-messenger action of NO and arachidonic acid. Experimental evidence that NMDA receptor blockers (*D*-AP-5) interrupt the acquisition of information, and that AMPA receptor agonists, such as 1-(1,3-benzodioxol-5-ylcarbonyl)-piperidine, facilitate memory retention, confirms the interrelation between LTP, learning, and memory and shows promising perspectives for "memory" drugs design [7, 54].

*Excitotoxicity* appears when energy metabolism is compromised and leads to acute neurodegeneration. Depletion of energy stores affects the ability of energy-dependent ionic pumps to maintain resting membrane potential and, subsequently, the depolarization of presynaptic neuron triggers action potentials, release of glutamate in the synaptic cleft, and postsynaptic AMPA and NMDA receptor activation. The increased influx of $Ca^{2+}$ through glutamate receptors triggers cytosolic calcium dyshomeostasis and the cascade of neuronal death. Some neuroprotective drugs, such as ifenprodil, appear to be NMDA receptor blockers. Chronic glutamate receptor activation has been implicated in some neurodegenerative disorders, such as ALS, Huntington's chorea, and olivopontocerebellar atrophy. Recent demonstration of the topology of receptor subunits and the identification of the major structural domains responsible for ion permeability suggests that new therapeutic strategies must be targeted at the molecular diversity of these receptors [44, 54, 73–75].

### 6.5 Catecholamines

Catecholamines are a group of important neurotransmitters or hormones that contain a catechol nucleus and an amine group. They consist of norepinephrine (NE), epinephrine (EPI), and dopamine (DA).

***Norepinephrine*** NE is a neurotransmitter in both CNS and PNS, EPI is a hormone released from the adrenal gland, and DA serves as neurotransmitter in some important pathways that form together the dopaminergic brain.

The noradrenergic neurons, clustered in the brain stem reticular formation (FR), are organized into three different nervous cell populations. The dorsal one (A6 and A4) located in the upper lateral aspect of the rhomboid fossa is represented by locus coeruleus, considered the main brain catecholamine source. Their long axons project to the spinal cord, the cerebellum, the diencephalon, and the cerebral cortex and belong to the activatory system of FR, which is involved in attention, arousal, and vigilance. The lateral tegmental noradrenergic neurons (A1, A5, and A7) and the dorsal medullary group (A2) project to the brain stem nuclei and hypothalamus and are involved in feeding behavior and hunger regulation. Peripheral noradrenergic cells are located in sympathetic ganglia and in the adrenal medulla [54].

The precursor of catecholamine biosynthesis is L-tyrosine. Through the action of tyrosine hydroxylase results L-DOPA, which is decarboxylated to dopamine by DOPA decarboxylase. For all neurons that synthesize EPI or NE, DA serves as an essential precursor. DA by action of dopamine β-hydroxylase forms NE, which is converted to EPI by phenylethanolamine *N*-methyltransferase. The first step of the biosynthetic pathway, prior to dopamine formation, occurs in the cytosol. DA is taken up into storage vesicles and the final β-hydroxylation takes place within vesicles in the noradrenergic neurons. NE is released into the synaptic cleft by calcium-dependent exocytosis and is taken up into the axon terminal by an $Na^+/Cl^-$-dependent membrane transporter [7].

The life cycle of NE may be interfered as follows [2, 7, 28, 76]:

***T2.*** Enzymatic synthesis may be blocked by α-methyltyrosine, a competitive inhibitor of tyrosine hydroxylase. The dopamine β-

hydroxylase is blocked by Fla-63, a dithiocarbamate derivative.

***T3.*** The mechanism of uptake and storage of the catecholamines into synaptic vesicles is interfered by reserpine and tetrabenasine.

***T4.*** The release of NE is increased by amphetamine that blocks the reuptake mechanism.

***T7.*** The reuptake of NE is inhibited by the tricyclic antidepressive drug desipramine.

***T9.*** In the presynaptic boutons NE is degraded by MAO, which is inhibited by the antidepressive drug pargyline.

The opportunities to interfere with the life cycle of NE, inside the CNS, are restricted by the abundant distribution of the receptors in various peripheral territories, by the low ability of known adrenergic agonists and antagonists to cross the BBB, and by the lack of specificity of various compounds for postsynaptic central neuron receptors.

***Dopamine*** For a long time, dopamine was considered to be an intermediate in the biosynthesis of NE. The discovery of significant levels of dopamine inside the brain, especially confined to the basal ganglia, and thereafter important striatal dopamine depletion in the PD, led to the hypothesis that dopamine might be involved in the control of the motor system.

Dopamine is estimated to form over 80% of the total brain catecholamine content. The dopaminergic nerve cells are classified into A8–A15 neuronal populations and are located in the brain stem and the diencephalon. Functionally, they are organized into *short systems* of amacrine-like interneurons of the retina and olfactory bulb, *intrahypothalamic system* (tuberohypofisial, incertohypothalamic, medullary periventricular projections) and *long systems* that link substantia nigra and ventral tegmental area (the main dopamine sources of the brain) to the neostriatum, the limbic cortex, and other limbic structures (olfactory tubercle, nucleus accumbens septi, amygdalae, and piriform cortex) [7, 54].

The life cycle of dopamine may be interfered with as follows: the DOPA decarboxylase is inhibited by NSD-1015; the DA uptake and storage is inhibited by reserpine, tetrabenazine, and meperidine analog. Amphetamine increases dopamine release and blocks DA reuptake. Cocaine also blocks DA reuptake and stimulates the DA release. Nomifensine and glutamate-binding protein (GBP) are DA reuptake blockers only [7, 44, 51].

DA receptors may be classified into $D_1$ and $D_2$ subtypes. The $D_1$-like receptor family includes $D_1$ and $D_5$, which stimulate the activity of adenylyl cyclase (AC) and have high affinity for benzazepines (antagonist SCH 23390) and low affinity for benzamides. Of the two types, $D_5$ receptors have higher affinity for DA. The $D_2$-like receptor family comprises $D_2$, $D_3$, and $D_4$ receptor and inhibits AC. Compared with $D_2$, the $D_3$ receptor has a higher affinity for the antiparkinsonian drugs quinpirole and pergolide, as well as for DA autoreceptor inhibitors (+)-UH232 and (+)-AJ76. The $D_4$ receptor has a particularly high affinity for clozapine and is considered a rational target for antipsychotic drug design (Table 5) [2, 7, 44, 77–79].

The action of some drugs on dopamine turnover [2, 7, 44]:

1. *Major tranquilizers.* The phenothiazine and butyrophenone antipsychotic classes increase the brain dopamine turnover, blocking both dopamine autoreceptors and postsynaptic dopamine receptors, and it has been suggested that excessive mesolimbic dopaminergic activity might be involved in the pathogenesis of schizophrenia.
2. *Minor tranquilizers.* The anxiolytic drugs interact preferentially with mesoprefrontal dopaminergic neurons and their effect might be attributed to GABAergic facilitation.
3. *Antidepressants.* The MAO inhibitors increase the endogenous levels of both brain DA and NE. The tricyclic antidepressants interact with noradrenergic neurons, while the atypical antidepressants do not have a selective interaction with the dopaminergic system.

**TABLE 5 Dopamine Receptors Ligands**

| Receptor Family | Selective Agonist | Selective Antagonist | CNS Location |
|---|---|---|---|
| $D_1$ | SKF 38393, fenoldopam, dihydrexidine | SCH 23390, NNC-112 | Striatum, NAc, OT, SN |
| $D_2$ | Quinpirole, RU 24926, EMD 23448 | Haloperidol, pimozide, (−)-sulpiride, domperidone, spiperone, raclopride | Striatum, NAc |
| Autoreceptor | 3PP, EMD 23-448 | (+)-UH 232, (+)-AJ 76 | Somatodendritic membrane and terminal boutons of dopaminergic neurons |

### 6.6 Histamine

Histamine is a biogenic amine involved in various allergic and inflammatory reaction but also in behavior regulation and in the action of some psychotropic drugs. The histaminergic neurons are located in the posterior, tuberomamillary part of the hypothalamus and are divided into five subgroups designated $E_1$–$E_5$ [80]. These small cell clusters are connected afferently with the prefrontal cortex, the medial preoptic area, and the septum and send diffuse projections to other hypothalamic nuclei, the cerebral cortex, the hippocampus, the olfactory bulb, the amygdalae, the medial septum, the cerebellum, and the brain stem. The co-localization of GABA, substance P, galanin, met-enkephalin, and brain natriuretic peptide in the histaminergic neurons of tuberomamillary nucleus has also been demonstrated [81, 82].

In the brain, histamine is synthesized from histidine by the action of histidine decarboxylase and catabolized by histamine methylltransferase, and monoamine oxidase The histamine receptors are divided into three classes: $H_1$, $H_2$, and $H_3$ (Table 6).

The significance of brain histamine receptors for neuroprotective drug design includes the sedative properties of some $H_1$-blocking antihistaminic agents, the opioid-mediated analgesia related to $H_2$ receptor antagonists, and agonist/antagonist $H_3$ receptors manipulation in order to modulate arousal, appetite, seizure threshold, and some cognitive processes [54, 81].

## 7 NEW TARGETS AND APPROACHES FOR CNS THERAPY

### 7.1 Novel Insights into the Mechanism of Action of Known Drugs

Selegiline (*N*-propanyl-*l*-amphetamine; *l*-deprenyl) is a selective irreversible inhibitor of MAO-B used to treat PD. It has been demonstrated that its neuroprotective properties are also mediated by the suppression of free radical formation elicited by glutamate, upregulation of the antioxidative enzymes (SOD and catalase), induction of proteins interfering with the apoptotic pathway, and the modulation of the expression of neurotrophic factors and of GAPDH and other redox active molecules (thioredoxin). From this point of view, selegiline might represent a model for the development of new neuroprotective *N*-propargyl analog [83].

Minocycline, a second-generation, orally bioavailable and BBB-permeable tetracycline, exhibited remarkable neuroprotective properties due to direct inhibition of cytochrome c release and of the downstream events related to cell death (in particular, the activation of caspase 3 and caspase 1); inhibition of ischemia-induced nitric oxide synthase, of matrix metalloproteinase MMP9 during acute ischemic stroke, and of reactive microgliosis. These effects, demonstrated in mouse models of neurodegenerative disorders and ischemic and traumatic brain injury, are currently investigated in clinical trials for HD and ALS [8, 84]. Tetracycline-based antioxidants, such as 12*S*-hydroxy-1,12-pyrazolinominocycline, devoid of antibiotic activity, have also shown neuroprotective properties in oxidative stress-mediated complications [85].

### 7.2 NOS Inhibitors

In the acute ischemic brain, nitric oxide synthase (NOS) activity is greatly increased, and nitric oxide (NO) rapidly reacts with superoxide to form peroxynitrite, which is a powerful oxidant and highly cytotoxic [16]. It is assumed that NO released by neuronal isoform nNOS would play a major role in ischemic neurotoxicity. The inducible enzyme iNOS could be the major source of delayed NO release in the ischemic brain contributing to further neuronal injury, whereas endothelial eNOS would have a neuroprotective effect. Therefore, nNOS and iNOS seem to be the proper therapeutic targets for pharmacological manipulation of NO activity in acute cerebral ischemia in a defined time window [86].

The dual role of brain nitric oxide in neurodegeneration/neuroprotection and its complex involvement in both brain physiology (brain development, synaptic plasticity, learning, memory) and pathology, as well as the potential role of therapeutic target in stroke, neuroinflammation, and neurodegenerative disorders, are illustrated in Contestabile et al. [87], Hobbs et al. [88], and Mena et al. [89].

**TABLE 6 Histamine Receptors Agonists and Antagonists**

| Receptors | Agonist | Antagonist |
|---|---|---|
| $H_1$ | 2-(*m*-Bromophenyl)-histamine | Mepyramine, *trans*-triprolidine |
| $H_2$ | Amthamine, impromidine | Ranitidine, tiotidine |
| $H_3$ | (R)-α-methylhistamine, (R)-α,(S)-β-dimethylhistamine, imetit | Thioperamide, clobenpropit |

The rational design of isozyme-specific NOS inhibitors for ischemic stroke in humans is based upon a combined crystallographic and computational docking approach [90–92]. The neuroprotective effects of nitroindazole derivatives, especially 3-bromo-7-nitroindazole and 7-nitroindazole, are mainly due to selective inhibition of nNOS but also to MAO-B inhibition [93, 94] and have been demonstrated in animal models of stroke, PD, and brain injury [16, 95, 96]. Their neuroprotective efficacy is dependent on the dose, phase, and severity of cerebral ischemia-reperfusion injury and on ischemic brain acidosis [96–101]. For example, 7-nitroindazole has provided significant neuroprotection for hippocampal CA1 neurons during early reperfusion after transient forebrain ischemia [102] and has potentiated the anticonvulsant activity of phenobarbital, diazepam, and valproate [103].

The heterocyclic substituted amidine ARL 17477, as well as delta-(*S*-methylisothioureido)-L-norvaline (L-MIN), have been proven potent and selective inhibitors of nNOS, able to penetrate the BBB and to decrease the lesion volume after transient cerebral ischemia [104, 105]. Aminoguanidine derivatives are relatively selective iNOS inhibitors that have shown time- and dose-dependent neuroprotective effects, safety, and good tolerability after oral and intravenous administration in clinical trials [86].

### 7.3 Caspases Cascade Inhibition

Caspases are involved in the pathogenetic mechanism of neurodegenerative and neurological disorders as triggers of apoptotic neuronal death. Pharmacological inhibition of caspases activity, either by a broad caspase inhibitor or with semiselective inhibitors of caspase 1 and caspase 3, has proven neuroprotective effects only for neuronal cells from the penumbra of the ischemic region afflicted by apoptosis [8].

### 7.4 Calpains Inhibitors

Increased proteolytic activity of the classical calpains (μ-calpain or calpain-1 and *m*-calpain or calpain-2) has also been involved in neurodegenerative diseases and ischemic and traumatic brain injuries. Among the substrates intensively cleaved by classical calpains are (a) tau protein and other neurofibrillary tangles' proteins abundant in the brain of AD patients; (b) huntingtin protein, generating toxic fragments responsible for neuronal loss; (c) protein p35, important in neural tissue development, converted to p25, that is responsible for the hyperphosphorylation of the tau protein, the latter becoming highly resistant to μ-calpain degradation; (d) α-synuclein, the major component of Lewy bodies in PD; and (e) αII-spectrin, myelin, and other cytoskeletal proteins [106–108].

Synthetic peptidic and nonpeptidic calpain inhibitors have shown promising neuroprotective effects in animal models. In order to improve potency, cell permeability, and selectivity, the third generation of calpain inhibitors, such as peptidyl ketoamides, morpholine derivatives, benzodioxothiazines, and chromones, were developed. The α-mercaptoacrylic acids are nonpeptidic, reversible noncompetitive inhibitors from the fourth generation, with improved stability, selectivity, and pharmacological profile compared with the peptidic inhibitors. To overcome their modest ability to cross the BBB, calpain inhibitors were coupled with molecules (such as taurine, L-aminocarnitine) that have specific carriers in the brain [106, 109–111].

### 7.5 Other Targets and Neuroprotective Agents

The significance of other potential targets in CNS diseases and the related pharmacological neuroprotective attempts are exemplified in Table 7.

## 8 DEVELOPMENT OF NEUROPHARMACEUTICALS FOR ALZHEIMER'S DISEASE

### 8.1 Introduction

AD, the most common neurodegenerative disorder, currently afflicts over 8 million people worldwide, 4–5 million Americans, 5–10% of the population over the age of 65, and 30–50% over the age of 85 [5, 130]. Each year 360,000 new cases of AD are developing, and the incidence of AD will double in the next 25 years as the proportion of the elderly population increases. It is estimated that all over the world more than 20 million people will be affected and the annual economic expenses will exceed $100 billion [131]. In the highly developed industrial countries Alzheimer dementia is the fourth most common cause of death after heart disease, cancer, and stroke [132].

The clinical debut of the disease is insidious, with impairment of recent memory and attention, progressive deterioration of language, abstract thinking, judgment, and alteration of personality. In the final stage of illness the patients, severely demented, lose all psychomotor abilities including grasping and suckling reflexes.

AD is a global subcortico-cortical disconnection with the hippofunction of the basal forebrain cholinergic system due to neuronal loss in the basal nucleus of Meynert, the medial septal nucleus, and the nucleus of diagonal band Broca. Nerve cell death in these areas

**TABLE 7 Other Potential Targets and Therapeutic Approaches for CNS Disorders**

| Targets | Pathological Significance | Therapeutic Approaches | References |
|---|---|---|---|
| SOD | Oxidative stress-induced neurotoxicity | Extracellular-SOD mimetics; Cu/Zn SOD gene delivery | 112, 113 |
| JNK, p38MAPK, MLKs | Stress-activated protein kinases in neuronal death, upstream regulatory kinases of JNK | CEP-1347—the most advanced MLK inhibitor in clinical trials for PD | 114, 115 |
| CDK5 | Apoptosis and neurodegeneration | CDK5 inhibitors: flavopiridol roscovitine | 116 |
| GSK-3 | Increased activity in neuronal apoptosis, amyloid metabolism, tau protein hyperphosphorylation | GSK-3 inhibitors: lithium | 117, 118 |
| JAK2-STAT5 axis | Antiapoptotic, antioxidant effects | Neuroprotective recombinant human EPO (rh-EPO) | 119 |
| Cannabinoid system | Neurodegeneration | Cannabinoid receptors agonists; Potent and selective inhibitors of the endocannabinoid transporter | 120–123 |
| Neurosteroid nuclear receptor in Purkinje neurons | Promotion of dendritic growth, spinogenesis, synaptogenesis, and neurogenesis | Neurosteroid replacement therapy: allopregnanolone (3α,5α-tetrahydroprogesterone) | 124–126 |
| Adenosine receptors | Striato-pallidal neurons degeneration | Neuroprotective adenosine $A_{2A}$ antagonists | 127 |
| Ubiquitin-proteasome system | Neuronal development, synaptic plasticity | Inhibition of ubiquitin-rich protein aggregates | 128 |
| GLP-1 receptors | Neurotrophic properties on cholinergic neurons in the basal forebrain of the rat against Aβ and glutamate-induced apoptosis | GLP-1 agonists | 129 |

determines cholinergic denervation of amygdala, entorhinal, dentate, and hippocampic cortices and triggers a *domino effect* with important neuronal loss, anterograde in frontal and temporal neocortex, and retrograde in locus coeruleus, raphe nuclei, and other brainstem nuclei.

The diagnosis of AD is based on characteristic clinical features associated with distinctive histopathological lesions of neuronal cytoskeleton, the neurofibrilary tangles (NFT), and abnormal deposits of amyloid into extracellular matrix, senile plaques (SP), neuropil threads (NTh), Hirano bodies, and granulovacuolar bodies.

### 8.2 Pathogenesis

Despite its ethiological heterogeneity, therapeutic strategies arise from understanding the molecular bases of pathogenesis. It is difficult to identify an outstanding *primum movens,* precocious and singular, that could mark the disease onset.

***Genetic Defect*** For decades it has been known that 10–15% of cases of AD occur in an autosomal-dominant pattern and also that typical histopathological lesions AD-like were found in virtually all subjects with trisomy 21 (Down) who survived until their forties. Correlating this information, research focused on supposed genetic factors and demonstrated point mutation in the gene that encodes β-amyloid precursor protein (βAPP). This disease-causing gene is located on the long arm of chromosome 21 and induces the increased production of Aβ42 peptides or total Aβ peptides, thus triggering the amyloid cascade [133]. This hypothesis was supported by the discovery in the mid-1980s of the diffuse Aβ deposits in the hippocampus, other limbic and association cortices, without neuronal or glial damage, in the brains of patients who had died of Down syndrome aged 10–20 years [54].

Shortly after the discovery of βAPP gene mutation there were identified *presenilin 1 (PS1)* and the highly homologous gene *presenilin 2 (PS2)*, located on the chromosomes 14 and 1, respectively. Missens mutations of these genes increase Aβ42 peptide production and characterize the early onset of familial AD [134, 135].

Further biochemical studies identified apolipoprotein E (ApoE), a cerebrospinal fluid protein capable of binding Aβ amyloid. The ε4 polymorphism of the ApoE

gene significantly increased the risk of late-onset familial AD development [136].

The candidate genes in AD are located near a well-established linkage peak on chromosome 9q22 and encode βAPP, presenilin 1 (PS1) and PS2, *tau* protein, and ubiquilin UBQLN1, respectively. Genetic polymorphism of APP, PS1, and PS2 is correlated to the early onset of familial AD, and the APOE4 genotype is associated with a shift to an earlier age at onset [12, 137]. Tau gene mutation causes frontotemporal dementia, progressive loss of neuronal cells, atrophy of the forebrain, and memory impairment [138]. There is a significant association between AD and various single-nucleotide polymorphisms in UBQLN1, a gene that interacts with PS1 and PS2 and is involved in proteasome degradation of proteins [12, 139, 140].

***Hypocholinergic Cascade*** The role of ACh in learning, memory, and attention was demonstrated both experimentally and clinically [140a, 141]. The key role in the molecular aspects of ACh action on the postsynaptic membrane is played by the muscarine receptors that act via G proteins and also participate in the βAPP processing by the following mechanism:

The $M_1$, $M_3$, and $M_5$ receptors activate the phospholipids that catalyze the hydrolysis of phosphatidylinositol with diacylglycerol (DAG) formation. DAG activates the PKC responsible for APP phosphorylation, thus triggering the secretion of the physiological, trophic form of Aβ.

Cholinergic synapses depletion determines hypofunction of muscarinic mChR receptors, perturbation of the mChR/G protein couple function, abnormal APP phosphorylation, increased secretion of Aβ toxic form, and its deposition as senile plaques. The restoring of the mChR function could prevent the abnormal phosphorylation and seems to be a positive neuroprotective perspective.

Emerging evidence suggests that AChE may play a role in abnormal neurite projection growth and also mediates the in vitro aggregation of β-amyloid protein, the major component of AD senile plaques [142].

***Amyloid Cascade*** Amyloid in senile plaque (SP) is composed by a portion of an integral membrane glycoprotein, the βAPP, that exists in three isoforms containing 695 ($APP_{695}$), 751 ($APP_{751}$), or 770 ($APP_{770}$) amino acids. The APP is involved in cell development, growth, and adhesion. It follows normal membrane dynamics and is processed by proteolysis into different fragments of the initial molecule [7]. The Aβ peptide is released by the action of γ secretase. The Aβ is a 40- to 42-amino-acids peptide released in a soluble form by normal neurons and glial cells and is present in the CSF and plasma, which suggests the existence of a brain-blood clearance [143].

The amyloid cascade is triggered by various genetic, endogen, and exogen factors that influence APP synthesis and processing, enhance the Aβ secretion, and reduce its clearance. Dysfunction of the Aβ clearance mechanism (receptor-mediated Aβ transport across the BBB and enzyme-mediated degradation) leads to Aβ accumulation in the brain of patients with sporadic or late-onset AD. Efflux of Aβ from brain to blood is mediated by lipoprotein receptor-related protein (LRP) and P-glycoprotein [144, 145]. Excess amounts of Aβ down-regulate LRP receptors and, on the other hand, significantly upregulate by a positive-feedback mechanism the expression of the receptors for advanced glycation end products (RAGE), which mediates Aβ influx from blood to brain in AD patients and in APP transgenic models of AD. Experimental and epidemiological studies clearly show the correlation between neprilysin and sequence variants of the insulin-degrading enzyme (IDE), the principal zinc metalloendopeptidases degrading Aβ, with the extent of the amyloid deposits in late-onset AD [145].

These dysfunctions determine the insolubilization of AD, β-folded oligomeric structure fibrillization (β sheet), and deposition as SP, with neurotoxic effects, neurotransmitter deficits, neuronal death, and all clinical signs of dementia [146, 147].

***Tau Protein Cascade*** Tau is a soluble microtubule binding protein that, together with tubulin, promotes the stability and assures the normal cycle of microtubule assembly and disassembly. Abnormal phosphorylation of tau protein results in insoluble paired helical filaments (PHFs) that are made up of hyperphosphorylated isoforms [148, 149]. The PHFs conglomerate as neurofibrillary tangles (NFT) in the neuronal soma, as neuropil threads (NTh) in the dendrites, and the dystrophic axons develop bulbous terminals [150]. Thus, the axonal transport is impaired and the synaptic output is diminished, compromising the viability of the neuron. As neurons die, the remaining NFTs mark like gravestones the site of lost nervous cells. The externalization of the NTFs after the neuronal death significantly increases the insolubility of SP.

***Excitotoxic Cascade*** The neurodegenerative effect of Aβ is exerted through the increasing of excitatory amino acid (EAA) amount as a result of glutamate receptors (GluR) decrease in the hippocampus [151]. This activates the acute excitotoxicity mechanisms that start with an initial calcium-independent process when magnesium ions block NMDA receptor, and continues with cytosolic calcium ion increase, hyperactivation of enzy-

matic systems (proteases, lipases, and nucleases), neuronal lysis, endogenous glutamate release, and the additional hyperactivation of glutamate receptors that amplify the excitotoxic phenomenon. The magnesium ions dissociation from NMDA receptors and important influx of calcium ions might be due to the disruption of the mitochondrial function and low production of ATP, typical mechanism for long-term neurodegeneration [152].

AD evolution and progressive degradation of cholinergic and glutamatergic systems may be partially compensated by activating other neurotransmitter systems as GABA and monoaminergic systems.

***Oxidative Cascade*** The disruption of cytoskeleton determines dyshomeostasis of cytosolic calcium, initiation of lipid peroxidation (LP), generation of reactive oxygen species (ROS) [153, 154], mitochondrial destruction, and energy depletion of the neurons. Numerous studies demonstrate that ROS are generated directly from the amyloid plaques and NTF or by activation of surrounding microglial cells [155]. Intracellular calcium released from the destroyed cytoskeleton increases ROS production and activates NOS. The role of NO is ambiguous because by formation of peroxynitrite it has a cytotoxic effect acting synergically with ROS, yet its neuroprotective effect has also been demonstrated [156]. It is also known that copper and iron dyshomeostasis have a substantial contribution to the oxidative neuronal damage [157].

***Apoptotic Cascade*** Apoptosis is a crucial physiological mechanism, tightly regulated, that maintains the equilibrium between cell division and cell death [158]. The molecular biochemical phenomena of apoptosis recognize triggers, activators, and amplifiers of endogenous regulation. It passes through premitochondrial, mitochondrial, and postmitochondrial phases. The last one is triggered by caspases and by calpains, distinct families of cysteine proteases. Caspases are cell death executors that inactivate the vital cell proteins and cleave the cytoskeletal proteins, stop DNA replication, destroy the structure of nucleus, and disintegrate the cell into apoptotic bodies. The other family of cysteine proteases, the calpains, naturally inhibited by calpastatine, increase proteolysis of neurofilament proteins during neuronal apoptosis [8, 108]. The interruption of apoptotic cascade and restoration of the mitochondrial function are future targets for anti-AD drugs design.

### 8.3 Therapeutic Strategies

The novel strategies in the design of new therapeutic agents for treatment and prevention of AD are based on molecular neurochemical dysfunctions, and they must be focused on the substitution of the hypofunctional cholinergic system, the activation of other neuroprotective neurotransmitter systems indirectly affected, the interference of Aβ metabolism and of the NFT formation, and the antitoxic, antioxidative, and anti-inflammatory neuroprotection [159, 160].

***Substitutive Cholinergic Therapy*** The first target of anti-AD therapeutic strategy is the primary affected cholinergic system. The compensation of ACh deficit was approached as follows:

**The increasing of ACh synthesis** is based on the *therapeutic augmentation of the ACh precursor choline*. Exogenous choline, phosphatidylcholine, and lecithine have stimulating memory properties and from this group today are in use Gliatilin (Italfarmaco) and Brezal (Sandoz) [161]. The other agent, now in clinical trials, acetyl-L-carnitine has the advantage of *stabilizing the mitochondrial function and lipid metabolism* [162].

**The stimulation of ACh release** may be realized by very different mechanisms. Thus linopirdine (DuP 996), now in clinical trials, acts through the *selective inhibition of presynaptic potassium channels* [163]. From a series of 4-substituted imidazole derivatives that demonstrated antidementia properties in animal models [164, 165], clobenpropit is a H3 *histamine receptor (HR) antagonist,* while Thioperamide (Glaxo) and GT-2016 (Gliatech) act as *H3-HR inverse agonists*. Iodoproxyfan, UCL-1390, and AQ-0145 agents, as well as imidazole derivatives, have similar effects [82, 166]. *Presynaptic choline reuptake* and *ACh resynthesis* is stimulated by the Mitsubishi Chemical Product MKC-231, which also has a neuroprotective effect by suppressing NO formation triggered by calcium influx.

**Acetylcholinesterase inhibitors** (AChEI) are, historically, the first and most widely experimented therapeutic attempt. Theoretically, the inhibition of AChE in the synaptic cleft results in a *potentiation of cholinergic receptor* activity, but it is dependent on the integrity of presynaptic neurons, and it will be proportionally reduced with cholinergic neuron loss in the late stages of AD.

Acetylcholinesterase inhibitor therapy in AD is characterized by the exclusive inhibition of the catalytic activity without influence on profound morphogenic effects on neuronal and synaptic architecture, lack of selectivity on AChE isoforms, the potential to aggravate certain conditions by elevating the levels of catalytically inactivated AChE (the rare isoform AchE-R "read-through") via the feedback loop, and individual differences in sensitivity and therapeutic response [28].

The first generation of AChEI Tacrine (Cognex), Amiridine (NIK-247), and physostigmine lack brain

specificity inhibiting another enzyme (butyrylcholinesterase) and have important side effects, such as hepatotoxicity and sedation. Their clinical efficacy (slowing decline in executive functions more than memory and cognition) is about 20–30% [167]. (−)-Phenserine tartrate, the phenylcarbamate derivative of (−)-physostigmine, is a selective, noncompetitive, potent, and long-lasting inhibitor of brain AChE, which reduced the secretion of Aβ in cell lines by translational regulation of βAPP mRNA via a noncholinergic mechanism. (−)-Phenserine tartrate has produced significant improvements in cognitive function and is well tolerated in patients with AD, currently being investigated in phase III clinical trials [168].

The second generation [169] of AChEI, designed to reduce the side effects and to increase brain specificity, includes rivastigmine, ENA 713 [170] (Novartis), Aricept/Donepezil [171] (Pfizer), galanthamine [172], and eptastigmine [173] (Jenssen and Mediolanum). These drugs are especially effective in the incipient stages of AD. A comparison of the above-mentioned drugs with more potent and efficacious therapeutic candidates that are currently in clinical trials or are ready to go into clinical trials, and the medicinal chemistry approaches toward designing better pharmaceuticals, is reviewed in Suh et al. [174].

Bayer realized a proform of dimethyl-2,2-dichlorvynilphosphate called metrifonate with slow release of the active component and long-term inhibition of AChE. Molecular modeling, docking, and ADMET studies were applied to the design of novel molecular hybrids of tacrine fused with donepezil as AChEI for future treatment of AD [175]. The design of more potent and selective inhibitors of choline acetyltransferase might be guided by the 3D quantitative structure–activity relationship (3D-QSAR) studies carried out using the comparative molecular field analysis (CoMFA), molecular docking scores (FlexiDock, FlexX), and comparative molecular similarity indices analysis (CoMSIA) methods [176, 177]. Recently, it was demonstrated that AChE accelerates fibrillization of the soluble Aβ and forms with Aβ a neurotoxic complex [178, 179]. These findings reveal a new mechanism of AChEI therapeutic activity [180].

**The ligands of muscarinic cholinergic receptors (mChR)** might be the source of anti-AD medicaments due to mChR involvement in the APP processing. The literature reports as potential antidementia drugs some quinuclidine derivatives [181]. These are either *agonists of $M_1$ subtype of mChR* such as AF-102-B and SB 202026 agents (Sabcomeline/Memric) or *$M_1$ agonist/$M_2$ antagonist* such as agent Lu 25-109. All these ligands showed therapeutic effects only in animal models of AD. Xanomeline (LY 246708), selective agonist of $M_1$ and $M_4$ mChR, is a more promising agent that has now entered clinical trials.

**The ligands of nicotinic cholinergic receptors (nChR)** are very important for cognitive processes of the limbic system because they are involved in the formation of working memory [182]. They are significantly decreased in AD and strategies using nChR ligands as potential antidementia drugs are now developing. A *selective agonist of α4β2 of nChR*, ABT-418, produced by Abbott Laboratories [183], has entered clinical trials and its analogs A-92824, A-84543, and A-85380 are also being investigated. Other nChR agonists, nefiracetam [184] and SIB 1553A [185], are also proposed as potential anti-AD drugs.

***Neuroprotective Properties of Other Neurotransmitter Systems*** Activation of these systems is an alternative therapeutic strategy that may act *synergistically with the direct cholinergic compensation* described above. The literature describes various compounds with significant antidementia effects that act particularly on GABAergic, monoaminergic, and glutamatergic systems.

Pronounced cognitive function improvement have been shown: valproic acid, *GABA enhancing* anticonvulsant agent that prevents calcium dyshomeostasis and cytoskeletal lesions, CGP-36742 (Ciba) *GABA-B receptor antagonist*, and Suritozol (Hoechst) *inverse agonist of GABA-A receptors* at benzodiazepine site [186–189].

The *inhibitors of monoamine oxidase B* (MAO-B) deprenyl and lazabemide, used in clinical practice as antiparkinsonian agents, have also demonstrated antitoxic action against βAPP, possible inhibition of NOS and antioxidant effects [189a, 190, 191].

In experimental animal models 8-OH-DPAT, a *selective agonist of 5-$HT_{1A}$ serotonin receptors*, and ondansetron, a *selective antagonist* of the same receptors, demonstrated antidementia protection via antiexcitotoxic effects and increasing of brain extracellular ACh [54]. Recent in vitro and in vivo pharmacological and biochemical studies have proven the role of 5-$HT_4$ receptors in cognitive processes and the APP processing, thus *selective 5-$HT_4$ agonists* may represent a new approach for the treatment of AD [192].

The involvement of the *glutamatergic system* in AD pathogenesis is suggested by the decreasing of hippocampal glutamate receptors (GluR) and by the ability of endogenous glutamate to induce the excitotoxicity resulting in neuronal death.

Memantine [194], *antagonist of NMDA receptors* and *agonist of AMPA* receptors, presented moderate anti-AD efficacy, but its specificity for phencyclidine site of receptors associated with psychomimetic effects restricts its use. In animal models, the agent CX516 belonging to

the ampakines group displayed cognition stimulating properties. D-Cycloserine, agonist of the glycine B site of the NMDA receptor, has the same promising properties on animal models [193]. Among the agents targeted at the glutamatergic system with favorable results in experimental AD models are sabelusole, which blocks glutamate-induced calcium influx and stabilizes the neuronal cytoskeleton, the natural glycoside gastrodin extracted from *Gastrodia elate*, which is a memory enhancer used in Chinese medicine, and taurine, which also blocks glutamate-induced calcium influx.

Small molecules that mimic the biological activity of NO, including NO donors, may ameliorate cognition and provide neuroprotection. GT 1061 is an NO chimera, an NO mimetic compound that contains an ancillary, synergistic pharmacophore currently in clinical trials. NO chimeras and hybrid nitrates hold promise as therapeutics for AD with multiple sites of action [195, 196].

***Interference of Amyloidic Cascade*** **Interference of Aβ formation** is the most rational therapeutic target to block the cascade of the neurodegenerative process. As the processing of APP regulated by mChR involves the proteolytic activity of β- and γ-secretases, the search of direct specific blockers seems the most attractive, but information is still missing [197–199]. The normalization of APP cleavage by stimulation of metabotropic glutamate receptors may be also used to prevent the development of Aβ [200].

Recently, monensin and brefeldin A were reported to decrease Aβ formation by destabilization of pH gradient and of vesicular transport. Bafilomycin A blocks the lysosomal acetyltransferase and indirectly inhibits the β-secretase activity, and leupeptine, novel isocoumarin JLK inhibitors, and compound E-64 are acting by inhibition of γ-secretase [201, 202]. The synthetic derivative DAPT reduces in vivo the brain level of Aβ.

Reduction of serum cholesterol level and normalization of cholesterol metabolism via the inhibition of *3-hydroxy-3-methyl-glutaryl-coenzymeA (HMG-CoA) reductase* was demonstrated to decrease the production of Aβ, and the statin agents (lovastatin, pravastatin, simvastatin, atorvastatin) are today used to decrease the prevalence of AD [203–207]. It was also attempted to delay or reverse the fibrillization of Aβ by interfering with the formation of β-folded aggregates [147, 208]. The functional role of antiparallel β sheets in the insoluble Aβ42 structure and the application of β-turn mimicking strategies in the design of novel therapeutic agents are discussed in Brakch et al. [209].

The aggregation and deposition of Aβ fibrils in the brain may be decreased by various compounds such as the glycoprotein laminin and laminin-related peptides [210, 211], Paroxetine [212], the antibiotics rifampicin, erythromycin, tetracycline, or daunomycin, the last binding to Aβ and blocking the amyloid fibrils formation [213, 214], or the antioxidant *N*-acetyl cysteine. Their chemical structures might be employed as starting points for AD drug design and development [212, 215]. Inhibition of Aβ fibril formation was also demonstrated for a newly synthesized benzofuran series, particularly for the compound SKF 74652 [214]. Recent studies have shown that short peptides like $A\beta_{15–22}$ prevent Aβ self-aggregation and may be useful in AD therapy [216].

Other targets of special interest emerge from the intervention of ApoE and ApoJ in the endogenous mechanism of amyloid fibril formation. Involved in the metabolism of lipids and lipoproteins, ApoE has several isoforms (E2, E3, and E4) and the allele *ε4* of the *APOE* gene is known as a genetic risk factor for AD. The neurodegenerative mechanism triggered by *ε4* involves the diminution of the Aβ efflux from neuron to extracellular space [217, 218]. Since the ApoJ protein stimulates the accumulation of the trophic form of amyloid, it is very attractive to influence the balance of ApoE/ApoJ in order to normalize the Aβ metabolism.

*Enhancing Aβ Clearance* Potential therapeutic strategies developed for enhancing the Aβ clearance from AD brain comprise: (a) promoting receptor-mediated Aβ efflux either by RAGE-specific IgG or statins (simvastatin, lovastatin) [219]; (b) upregulating enzyme-mediated Aβ degradation through neprilysin or IDE gene therapy and pharmacological activation (somatostatin and somatostatin receptor agonists) [220]; (c) immunotherapy [145]; and (d) peripheral treatment with Aβ-bindable substances (gelsolin, curcumin, enoxaparin), which favor soluble Aβ species much more easily eliminated [221].

*Immunotherapy* is another approach of AD therapy because it suppresses the formation of β-amyloid, dissolves already formed fibrillar amyloid, and delays learning and memory deficits in mice [222–224]. Active immunization with $A\beta_{1–42}$ in humans was stopped in phase II clinical trials due to frequently developed adverse reactions, such as autoimmune meningoencephalitis and cerebral hemorrhage [145, 222].

New $A\beta_{1–15}$ or $A\beta_{42}$ peptides or Aβ DNA vaccines and antibodies toward the EFRH sequence (glutamate-phenylalanine-arginine-histidine sequence) improve memory and cognition in AD animal models and in phase IIa clinical trials, and alleviate neuroinflammatory adverse reactions of classical immunotherapy [145, 225–227]. Passive immunotherapy with antibodies against Aβ, also endowed with α-secretase-like activity, reduces Aβ concentrations in CSF, improves cognitive function, and has proven to be much safer than the

active immunization and is in a phase I clinical trial in the United States [228, 229].

*Inhibition of NFT Formation* Since NFT, the other prominent AD morphopathological event, involves the abnormal hyperphosphorylation of microtubule-associated tau protein (MAP), the logical neuroprotective strategy seems to be either the inhibition of tau-phosphorylase/proteinkinase or the activation of tau-phosphatase [149]. The information concerning such specific compounds is missing in the literature, lithium salts only being mentioned as inhibitor of glycogen synthase kinase-3, which catalyses tau protein phosphorylation [230]. Small-molecule inhibitors of tau aggregation, able to cross the BBB and to improve cytoskeletal integrity and neuron viability, such as a family of heat shock protein HSP90 inhibitors, might be identified by HTS [80, 150].

*Interference of Aβ Neurotoxic Effect* As has been shown, the intimate mechanisms of Aβ neurotoxicity are closely related to calcium dyshomeostasis, and the attempts to stabilize the calcium homeostasis of neuron would have beneficial effects on neuronal survival. The anticalcium strategy is thus justified and agents such as nimodipine, blocker of L-type calcium channels and the antagonists of ryanodine receptors that regulate the levels of cytosolic calcium, are waiting for clinical trials [231].

***Antioxidant Therapy*** For a long time the theory of oxidative stress has occupied a central place in the ethiology of AD and offers strong arguments for antioxidant therapy for this type of dementia [232]. The morphologic intact neuron has *endogenous systems* that protect it from higher than normal NOS levels and stimulation of these systems is an opportune target for AD treatment. Recently, it has been shown [233] that the nuclear transcription factor NF-κB, which increases during oxidative stress, is able to induce the transcription of genes encoding catalase and glutathion peroxidase, enzymes that protect the cell against Aβ neurotoxicity.

An alternative neuroprotective strategy should be the application of external antioxidants that block ROS action. The presence of functional groups able to accept oxygen radicals or free electrons and the penetrance through the BBB are the most important conditions for a molecule to be an antioxidant. Vitamin E and its synthetic analog idebenone have been demonstrated to delay the involution of AD. Other synthetic analogs of α-tocopherol, IRF 10016 and MDL 74180DA, also have antioxidant properties now being tested in preclinical studies [232a].

Another antioxidant described in the literature as a promising agent for dementia therapy is the extract of *Ginkgo biloba* ECB761, which neutralizes NO radicals and exhibits neuroprotective properties in animal models. Celastrol, herbal tripterine, has strong antioxidant and anti-inflammatory activity and significantly stimulates learning and memory in animals with experimentally induced dementia [234].

Antioxidant properties are displayed by steroid hormones and their derivatives, which activate specific hormonal receptors, modulate neurotransmission, and may be synthesized in the neurons. The most widely studied are estradiol and its derivatives [235, 236], Estraderm (Novartis) and J811 and J861 (JenaPharm), which have pronounced neuroprotective properties and enhance cognition [237–239].

Melatonin, the hormone of the pineal gland, interacts with hydroxyl radicals and through antioxidant effects regulates the processing of APP, inhibits the formation of amyloid fibrils, and protects the neurons against excitotoxicity. *N*-acetylserotonin (NAS), the melatonin precursor, displays higher antiamyloid activity and radical-scavenger properties [240–242].

***Interference of Apoptotic Cascade*** As described above, the associated mitochondria peptides regulatory factor controls apoptosis by acting on mitochondrial calcium. The increased calcium influx into mitochondria during apoptosis may be blocked by the phenylhydrasone derivative p-trifluoromethoxy carbonyl cyanide phenyl hydrazone (FCPP), which acts as protonophor [243]. The muscle relaxant agent dantrolen demonstrated antiapoptotic activity modulating the interaction mitochondria/antiapoptotic protein Bcl-2 [244]. Bongkrekate and cyclosporine A inhibit the proapoptotic peptide Bax and the compound ALCAR (acetyl-L-carnitine) stabilizes the cell membranes and mitochondrial energy production [191, 245].

***Anti-inflammatory Therapy*** Anti-inflammatory therapy is targeted at the late phase of AD pathogenesis when cytokines IL-1 and IL-6 activate the complement cascade, and anaphylatoxin activates microglia. The cyclo-oxigenases (COXs), prostaglandin endoperoxide H synthase, and lipoxygenases act on arahidonic acid and generate eicosanoids (prostaglandins and leucotrienes), the very active mediators of inflammation. All these processes may potentiate the neurotoxic effect of Aβ, trigger ROS formation, and activate microglia.

It has been demonstrated that the nonsteroidal anti-inflammatory drugs ibuprofen and naproxen [246] decrease the risk of AD by nonselective inhibition of COXs. Rofecoxib (Merck), selective inhibitor of COX-2, is also investigated as a potential anti-AD drug.

Ibuprofen, indomethacin, and flurbiprofen, by combining anti-inflammatory and antiamyloidogenic properties, have proven to have direct Aβ-lowering effects in cell cultures as well as transgenic models of AD-like amyloidosis [247]. A novel, integrative chemical/biological approach for the rapid discovery of potential lead compounds targeting neuroinflammation is described for synthetic libraries containing pyridazine molecular fragment, allowing the identification of orally bioavailable compounds with the desired physical properties and in vivo activity [248]. Among other anti-inflammatory agents with promising anti-AD effects, prednisone, hydroxychloroquine, and colchicine are mentioned in the literature [249–251].

## Abbreviations

| | |
|---|---|
| Aβ | β-amyloid |
| AC | adenylyl cyclase |
| ACh | acetylcholine |
| AChE | acetylcholinesterase |
| AChEI | acetylcholinesterase inhibitors |
| AD | Alzheimer disease |
| ADMET | absorption, distribution, metabolism, toxicity |
| ADNF | activity-dependent neurotrophic factor |
| ADNP | activity-dependent neuroprotective protein |
| ALS | amyotrophic lateral sclerosis (Lou Gehrig's disease) |
| AMPA | α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid |
| AP-5 | 2-amino-5-phosphonopentanoic acid |
| AP-7 | 7-amino-phosphonoheptanoic acid |
| ApoE | apolipoprotein E |
| ApoJ | apolipoprotein J |
| βAPP | β-amyloid precursor protein |
| 3-APPA | 3-aminopropylphosphinic acid |
| BBB | blood–brain barrier |
| BDNF | brain-derived neurotrophic factor |
| CaM-KII | calcium/calmodulin-dependent protein kinase II |
| 5-CAT | 5-carboxamidotryptamine |
| CDK5 | cyclin-dependent kinase 5 |
| CNQX | 6-cyano-7-nitroquinoxaline-2,3-dione |
| CNS | central nervous system |
| CNTF | ciliary neurotrophic factor |
| CoMFA | comparative molecular field analysis |
| CoMSIA | comparative molecular similarity indices analysis |
| COXs | cyclo-oxigenases |
| CPP | 3-(2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid |
| CSF | cerebrospinal fluid |
| DA | dopamine |
| DAG | diacylglycerol |
| 4-DAMP | 4-diphenylacetoxy-*N*-methylpiperidine |
| DATP | *N*-[*N*-(3,5-diflorophenacetyl)-L-alanyl]-*S*-phenylglycine, *t*-butyl ester |
| DNA | deoxyribonucleic acid |
| DNQX | 6,7-dinitroquinoxaline-2,3-dione |
| DOB | 2,5-dimethoxy-4-bromoamphetamine |
| DOI | 2,5-dimethoxy-4-iodoamphetamine |
| 3D-QSAR | 3D quantitative structure–activity relationship |
| EAA | excitatory amino acids |
| ECB | extract of *Ginkgo biloba* |
| ECF | interstitial or extracellular fluid |
| EFRH | sequence-glutamate-phenylalanine-arginine-histidine sequence |
| EGF | epidermal growth factor |
| EPSPs | excitatory postsynaptic potentials |
| FCCP | p-trifluoromethoxy carbonyl cyanide phenyl hydrazone |
| FGF-1, -2 | fibroblast growth factors |
| FR | reticular formation |
| GABA | γ-aminobutyric acid |
| GABA-T | GABA aminotransferase |
| GAD | glutamate acid decarboxylase |
| GAPDH | glyceraldehyd-3-phosphate dehydrogenase |
| GBP | glutamate-binding protein |
| GDNF | glial cell-line-derived neurotrophic factor |
| GLP-1 | glucagon-like peptide-1 |
| GluR | glutamate receptors |
| GSK-3 | glycogen synthase kinase-3 |
| HA-966 | 3-amino-1-hydroxypyryolid-2-one |
| HAT | histone acetyl transferase |
| HD | Huntington's disease |
| HGF | hepatocyte growth factor |
| HIR | human insulin receptor |
| HMG-CoA | 3-hydroxy-3-methyl-glutaryl-coenzyme A |
| 5-HT | 5-hydroxytryptamine |
| HTS | high-throughput screening |
| IDE | insulin-degrading enzyme |
| IFN-β | interferon-β |
| IGF-I, -II | insulin-like growth factors |
| IL-1 | interleukin-1 |
| $IP_3$ | phosphatidylinositol triphosphate |
| IPSPs | inhibitory postsynaptic potentials |
| JNK | c-Jun N-terminal kinases |
| L-687,414 | R(+)-cis-β-methyl-3-amino-I-hydroxypyrrolid-2-one |

| | |
|---|---|
| L-AP4 | L-2-amino-4-phosphonobutanoic acid |
| LIF | leukemia inhibitory factor (or cholinergic differentiation factor) |
| LP | lipid peroxidation |
| LRP | lipoprotein receptor-related protein |
| LSD | lysergic acid diethylamide |
| LTP | long-term potentiation |
| MAb | monoclonal antibody |
| MAO-B | monoamine oxidase B |
| MAOIs | monoamine oxidase inhibitors |
| MAP | microtubule-associated tau protein |
| mChR | muscarinic cholinergic receptors |
| *m*-CPBG | *m*-chlorophenylbiguanide |
| MCPG | α-methyl-4-carboxyphenylglycine |
| MLKs | mixed lineage kinases |
| MMP 2, 9 | matrix metalloproteinases |
| MNQX | 5,7-dinitroquinoxaline-2,3-dione |
| mRNA | messenger RNA |
| MS | multiple sclerosis |
| NAc | nucleus accumbens septi |
| NAP | nucleosome assembly protein |
| NAS | *N*-acetylserotonin |
| nChR | nicotinic cholinergic receptors |
| NFT | neurofibrillary tangles |
| NF-κB | nuclear transcription factor |
| NGF | nerve growth factor |
| NMDA | *N*-methyl-D-aspartic acid |
| NNC-112 | 3-methyl-1-(7-benzofuranyl)-2,3,4,5-tetrahydro-8-chloro-7-hydroxy-(1H)-3-benzazepine |
| NO | nitric oxide |
| NOS | nitric oxide synthase (endothelial eNOS, neuronal nNOS, inducible iNOS) |
| NT | neurotrophin |
| NTAK | Neural- and Thymus-derived Activator for ErbB Kinases |
| NTh | neuropil threads |
| 8-OH-DPAT | 8-hydroxy-dipropylaminotetraline |
| OGN | (antisense) oligonucleotides |
| OT | olfactory tubercle |
| p38MAPK | p38 mitogen-activated protein kinase |
| PD | Parkinson's disease |
| PDGF | platelet-derived growth factor |
| PHFs | paired helical filaments |
| PINK1 | PTEN-induced putative kinase-1 |
| PKC | protein kinase C |
| PNA | peptide nucleic acids |
| PNS | peripheral nervous system |
| PS1, PS2 | presenilin 1, presenilin 2 |
| RAGE | receptors for advanced glycation end products |
| RMT | receptor-mediated transcytosis |
| RNA | ribonucleic acid |
| RNase H | ribonuclease H |
| ROS | reactive oxygen species |
| SCH 23390 | 3-methyl-1-phenyl-2,3,4,5-tetrahydro-7-chloro-8-hydroxy-(1H)-3-benzazepine |
| SKF 38393 | 1-phenyl-2,3,4,5-tetrahydro-7,8-dihydroxy-(1H)-3-benzazepine |
| SN | substantia nigra |
| SOD | superoxide dismutase |
| SP | senile plaques |
| SSADH | succinic semialdehyde dehydrogenase |
| SSRI | selective serotonin reuptake inhibitors |
| TBPS | *t*-butylbicyclophosphorothionate |
| TCA | tricyclic antidepressants |
| TfR | transferrin receptor |
| TGF-α, -β | transforming growth factor-α, -β |
| TNF-α | tumor necrotic factor-α |
| UBQLN1 | ubiquilin |
| UCH-L1 | ubiquitin C-terminal hydrolase L1 |

## 1 INTRODUCTION

Alzheimer disease (AD) is the most prevalent neurodegenerative disease worldwide and affects over 4 million Americans [1]. As the average life expectancy increases in the United States and throughout the world, so does the number of elderly men and women who become increasingly susceptible to AD as they age. In fact, it is estimated that by 2050, 14 million Americans will have AD if preventative treatments do not become available [2]. The cost of treatment is considerable: National direct and indirect cost of caring for AD patients have been estimated to be upward of $100 billion per year, a figure that will rise as the prevalence increases [3].

AD is characterized by two basic neuropathological lesions, the senile plaque and the neurofibrillary tangle. The major protein component of the senile plaque is amyloid-β (Aβ), while the major protein component of the neurofibrillary tangle is hyperphosphorylated tau [1]. It is important to point out, however, that our understanding of the neuropathology of AD is based upon autopsy examination of end-stage disease. Thus, plaques and tangles are not "diagnostic" of AD; indeed, they may be seen in variable, and often large, numbers in cognitively intact elderly individuals. Rather, they are quantitative phenomena, being relatively more numerous in AD compared to controls. Application of standard criteria, therefore, yields a spectrum of diagnostic certainty in the case of Consortium to Establish a Registry for Alzheimer's Disease (CERAD) or National Institute on Aging (NIA)-Reagan criteria [4, 5], or a spectrum of stages in the case of Braak criteria [6]. It is also interesting to note that among the various neurodegenerative diseases, the one with the greatest overlap with "normal" aging, and the one with the most diagnostic uncertainty, is AD. Degenerative tauopathies such as corticobasal degeneration and progressive supranuclear palsy, for example, are essentially impossible to confuse with normal aging pathologically; this is also the case for synucleinopathies such as multiple system atrophy. Even Lewy body dementia, while nosologically cumbersome, is much more qualitative than classic AD. While Lewy bodies are described as age-related lesions, they are uncommonly seen in aged brains (i.e., are more "pathological"), whereas neurofibrillary tangles are essentially invariable in the medial temporal lobe of the elderly, as are amyloid deposits in the cerebral cortex.

In short, the diagnosis of AD on the basis of plaques and tangles at autopsy overlaps substantially with normal aging, and it follows that accumulation of plaques and tangles is as much an age-related process

as it is strictly pathological [7]. From the larger perspective, it makes much more mechanistic sense that accumulation of these proteins is more consequence than cause [8, 9]. Therapeutic targeting of earlier pathological processes is warranted for more effective therapy.

Ongoing investigations are aimed at targeting multiple metabolic abnormalities in AD. Such combinational drug therapies will hopefully reveal the effectiveness of drugs acting at multiple targets in the treatment of AD, rather than an isolated process, or an isolated protein that is more relevant to transgenic models and Mendelian conditions than it is to sporadic AD. In this review, we discuss a number of targets separately, namely Aβ, oxidative stress, lipid metabolism, inflammation, hormonal alterations with advanced age, phosphorylated tau, excitotoxicity, and cholinergic failure, bearing in mind that no one construct will likely represent the magic bullet for sporadic AD, and that multiple targets may give the greatest yield in the short term [10].

## 2 AMYLOID-β

Significant evidence in favor of the amyloid cascade hypothesis is the existence of familial "AD" in which germ line mutations in specific proteins lead to autosomal-dominant, early-onset AD. The specific proteins include amyloid-β protein precursor (AβPP) and presenilin-1 and -2. All three mutations affect processing of the Aβ peptides, and all are associated with prodigious accumulations of Aβ as well as neurofibrillary tangles with disease. Down syndrome subjects, who have an extra copy of chromosome 21 and, therefore, constitutively increased synthesis of AβPP, are predisposed to AD changes at a relatively young age. Down syndrome, therefore, represents another critical component of the amyloid cascade hypothesis.

Not surprisingly, a large body of knowledge regarding Aβ processing has accumulated. The Aβ peptide is a proteolytic cleavage product of AβPP, a type-1 transmembrane protein of unknown function. The two aspartyl proteases responsible for cleavage and conversion of AβPP to Aβ are referred to as β- and γ-secretases [11]. However, most AβPP molecules undergo cleavage by α-secretase, which cleaves this protein near the middle of the Aβ domain [12], resulting in a cleavage product with a large soluble ectodomain ($AβPP_s$-α) that is released into the extracellular space. The remaining C-terminal fragment can then be cleaved by γ-secretase to create a smaller fragment known as the p3 fragment. The function of such proteolytic processing in normal neurons has yet to be defined, although research has indicated that cleavage of AβPP by γ-secretase allows the release of the AβPP intracellular domain (AICD) to the nucleus where it is thought to participate in transcriptional signaling [11]. Cleavage of AβPP by β-secretase leaves a longer C-terminal fragment that is retained in the cellular membrane and is subjected to further cleavage by γ-secretase, which finally results in the Aβ peptide cleavage product.

β-Secretase has become an attractive therapeutic target because it initiates and is the rate-limiting step in the formation of Aβ (it is interesting to note that Aβ is constitutively secreted by mammalian cells and normally occurs in plasma and cerebrospinal fluid (CSF) [13, 14] ). Interestingly, inhibitors of β-secretase have similar chemical structures as AβPP. Sinha and Lieberburg developed StatV, a transition-state analog that spans the cleavage site of Swedish mutant AβPP for use as a β-secretase inhibitor [15]. OM99-2, a similar AβPP analog, was subsequently developed and is an even more potent β-secretase inhibitor. To date, however, available inhibitors are too large and lack sufficient specificity to be suitable for therapeutic use [16]. Since the discovery of presenilin-linked familial AD, the relationship between mutation and mechanism of AβPP processing has been the study of intensive investigation [17]. Early studies suggested that presenilin is a cofactor for γ-secretase [18] or that presenilin is itself a γ-secretase [19]. Later interpretations of experimental data indicated that presenilin is an unusual and unprecedented intramembrane-cleaving aspartyl protease [19]. Most recently, investigations utilizing genetic analysis of Notch signaling in *Caenorhabditis elegans* have revealed that γ-secretase is a multiprotein complex that has multiple regulatory subunits and that presenilin, nicastrin, aph-1, and pen-2 proteins are all required for γ-secretase activity [20, 21]. Nevertheless, regulation of presenilin and γ-secretase is still under investigation, and whether the extensive knowledge of the γ-secretase complex and its relationship with AβPP will translate into productive therapy remains to be determined.

As discussed, Aβ can normally be found in the CSF as a self-antigen, and cell-mediated immune responses would not be traditionally predicted to this peptide. Self-reactive T cells mediate a number of autoimmune diseases; however, no evidence exists showing deleterious effects of T-cell reactivity against Aβ. It has been established that activated T cells penetrate the Central Nervous System (CNS) [22] and that healthy elderly individuals and patients with AD have higher Aβ-reactive T-cell responses than middle-aged adults [23]. This suggests that the normal immune response includes an active response to remove excess Aβ from the brain. In light of this phenomenon, immunological approaches to clearing Aβ from the brain have been developed in recent years. Active immunization and passive immunization strategies have been studied, although only active

immunization has reached clinical testing. Briefly, findings regarding active immunization with synthetic intact Aβ1-42 were excellent in transgenic mouse models producing human Aβ. A significant reduction of Aβ plaques were reported in mice immunized before and after plaque development [24]. Additionally, immunization allowed these animals to regain functional effects [25, 26]. The underlying mechanism behind these beneficial reports has not been reported, however, one possibility is that reduction in Aβ deposition is due to Fc-receptor-mediated microglial phagocytosis [24]. Passive immunization strategy with antibodies raised against Aβ have suggested that microglia are responsible for clearing Aβ plaques through Fc-receptor-mediated phagocytosis and subsequent degradation [27]. Clinical trials were initiated to test tolerance to treatment in humans shortly after animal trials were completed. Synthetic peptide Aβ1-42 was combined with adjuvant (QS-21) to create the immunogen AN-1792 (Elan Pharmaceuticals/Wyeth). AN-1792 reached phase IIa clinical trials in the United States and Europe; however, the program was suspended in January 2002 when approximately 5% of the patients in the active treatment group developed meningoencephalitis [28].

While the Aβ peptide continues to be a popular target for new therapies, it is relevant that Aβ plaques have not proven to directly correlate with dementia and that plaque-producing transgenic models are not directly associated with neurological deficits. These inconsistencies have led to a modification of the amyloid cascade hypothesis that seeks to establish the pathogenecity of Aβ. Current research indicates that Aβ assembly of soluble oligomers has been implicated in the physical degeneration of synapses [29], and in vivo experiments have established that oligomers cause a failure in long-term potentiation (LTP) of neurons in the hippocampus. Exciting data has also come from human amyoid precursor protein (hAPP) transgenic mice and the ability of antibodies directed against pathogenic oligomers to reverse memory failure; this reversal of memory failure occurred without a reduction in plaques [30]. This phenomenon supported the concept that plaques are not responsible for neurological deficits, but rather oligomers are responsible for synaptic failure [31].

The Aβ oligomers shown to have the properties of disrupting LTP and synaptic degeneration are often referred to as oligomeric ligands or amyloid beta-derived diffusible ligands (ADDLs). Given the nature of ADDLs, they appear to be an excellent therapeutic target for the prevention and treatment of AD. These ADDLs uniquely influence short-term synaptic plasticity and long-term neuronal survival. They are also considered excellent therapeutic targets due to their regional specificity, especially since ADDLs target hippocampal but not cerebellar neurons [32]. In this regard, it should be noted that the vaccination approach may lead to *increased* levels of ADDLs [33].

## 3 OXIDATIVE STRESS

Multiple lines of evidence link oxidative stress and AD. Reduced glucose metabolism and mitochondrial abnormalities [34] are associated with AD as mitochondria are considered the source of oxidative stress. Oxidative phosphorylation produces superoxide radicals as a by-product associated with the electron transport. While most of these free radicals are sequestered in the mitochondria, oxidative insult is exacerbated by age, metabolic demand, and disease [35]. Heightened superoxide radical formation in AD also correlates with heightened superoxide dismutase (SOD) levels that may allow the release of $H_2O_2$ from the mitochondria to the cytoplasm. Mitochondrial abnormalities have also been associated with deficiencies in enzyme activities, specifically α-ketoglutarate dehydrogenase complex, pyruvate dehydrogenase complex, and cytochrome oxidase in AD neurons [36–38]. Increased $H_2O_2$ in the cytoplasm may cause a localized increase in the concentration of reactive oxygen species, especially in the presence of redox-active metals [39]. It has been shown that metals are dysregulated in AD [40] and that redox-active transition metals are aberrantly accumulated in the cytoplasm of AD-susceptible neurons [41].

A potential role for heavy metals in AD pathogenesis has been suggested in a number of studies; indeed, there is a close association between redox-active iron and pathological lesions in AD [42]. It has also been shown that Aβ and AβPP exhibit physicochemical interactions with micromolar and submicromolar concentrations of metal ions [43–46]. The pharmacological basis of chelation therapy and concomitant side effects, however, are complex and multifaceted; to date, reproducible therapeutic efficacy has yet to be shown [47]. Alternate approaches, using nanoparticle technology, may circumvent such aspects [48]. Also interesting with respect to metal ions is that the overall concentration of zinc is decreased in AD brain [49]. This metal has antioxidant activity and has been evaluated as a therapeutic agent to prevent production of reactive oxygen species.

It is also interesting to note that the Aβ peptide is a strong redox-active agent capable of reducing transition metals in the cytoplasm and allowing for the conversion of molecular oxygen ($O_2$) to $H_2O_2$ [50–52].

Antioxidant projection via vitamin supplementation is another avenue for long-term and safe treatments of AD. The most notable antioxidant treatment that is currently available is vitamin E supplementation.

Chemically *RRR*-α-tocopherol is the naturally occurring stereoisomer of vitamin E and is secreted by the liver due to specific binding by liver α-tocopherol transfer protein (α-TTP). Vitamin E has been demonstrated to be a lipid-soluble, chain-breaking antioxidant [53]. Vitamin regimens that include vitamin E and ascorbic acid (vitamin C) have indicated that consuming organic antioxidants may be beneficial. Some studies have found that antioxidants blunt the cognitive decline in AD or slow disease progression [54, 55]. A large epidemiological study showed that use of vitamins E and C in combination was associated with reduced AD prevalence and incidence [56].

## 4 LIPID METABOLISM

Recent studies suggest that it is possible to reduce cerebral Aβ levels in vivo with the Food and Drug Adminstration (FDA)-approved drug simvastatin [57]. The mechanism, however, is unclear, although the possibility that it may be related to apolipoprotein E is intriguing. Unlike molecular gene mutations, *Apo ε4* genotypes are not implicated in the generation of Aβ peptide; however, the *ε4* allele is associated with lowering the age of AD onset. Midlife high blood pressure and high cholesterol levels are associated with increased risk of developing AD later in life. While the data and mechanisms implicating cholesterol and lipid transport with development of AD are not well established, a number of studies indicate that the use of statins significantly reduces the risk AD [58, 59].

Experimentally, primary neurons treated with statins halt production of Aβ [60] and reduce the level of Aβ1-42. However, the mechanism underlying the action of statins remains unclear. Statins also act to decrease cellular cholesterol by inhibition of methylglutaryl coenzyme A (HMG-CoA). Given these simultaneous actions, it cannot be strictly stated whether statins or the reduction in membrane cholesterol are responsible for reduced Aβ levels.

## 5 INFLAMMATION

Exciting findings regarding the use of nonsteroidal anti-inflammatory drugs (NSAIDs) were originally reported in epidemiological data showing that classical NSAIDs could prevent or retard AD [61, 62]. Data based on positron emission tomography (PET) has shown that inflammation and activation of microglia are early pathogenic events that precede cerebral atrophy [63]. Additional evidence that inflammation mediates development of AD comes from studies demonstrating that inflammation from head trauma plays a role in initiating AD [64]. It is hypothesized that Aβ peptide is responsible for the innate immune response that occurs in AD patients. Additional findings suggest that Aβ deposition and plaque formation are associated with an innate immune response that includes activation of complement [65], secretion of pro-inflammatory cytokines, expression of chemokines, and excretion of nitric oxide, which mediates apoptosis [66, 67]. Experiments with transgenic mice show that the activation of the complement cascade may be beneficial for the brain [67]. However, a number of studies have shown that attenuating this inflammatory innate immune response may delay the onset and slow the progress of AD [68]. It appears that Aβ is responsible for activation of microglia and astrocytes since toxic forms of Aβ that are not completely removed induce chronic immune responses.

NSAIDs have been used extensively in medical practice and are currently prescribed for a number of inflammation-related ailments. NSAIDs downregulate the pro-inflammatory signals sent out by glia and astrocytes. In addition to anti-inflammatory action, NSAIDs have been shown to alter the production of Aβ1-42. It has been shown that some NSAIDs may reduce the risk of AD by lowering Aβ1-42. Production of Aβ1-42 is mediated through a pathway that involves a small G protein call Rho. NSAIDs have been shown to inhibit the activity of Rho and decrease Aβ1-42 production in transgenic mice. It has also been shown that NSAIDs that do not block Rho activity do not lower Aβ1-42 levels. The downstream effector proteins of Rho, Rock 1 and 2, are also pharmacological targets that could prevent Aβ1-42 production.

Epidemiologically, a number of case-control and population-based cross-sectional studies have been conducted to evaluate the relationship between the use of NSAIDs and the risk of AD. Data from a co-twin control study found an inverse relationship between anti-inflammatory treatments and AD [69]. The follow-up was conducted with siblings with a high level of familial AD and found that NSAIDs have protective effects [70]. Population-based studies have also suggested that anti-inflammatory drugs are protective against AD [71–73]. Whether these findings will translate into a change in the indications for NSAID therapy remains to be seen. Moreover, a thorough analysis of this data was undertaken by Launer, who concludes that no recommendation can be made concerning when or how a person can take NSAIDs to reduce risk of developing AD [74].

## 6 HORMONAL CHANGES WITH AGE

Some epidemiological gender studies concerning the prevalence and incidence of AD have indicated that

women have an almost twofold higher risk of developing AD [75]. Postmenopausal estrogen deficiency is hypothesized as a basis for the effect. This in turn has prompted the idea of hormone replacement therapy (HRT) as a possible treatment.

Early studies concerning the use of HRT as a treatment for AD came to divergent conclusions concerning HRT-based therapies. These findings were reported for therapy that included estrogen in addition to progestin regardless of time-course regimens. Evidence supporting the protective effects of HRT in postmenopausal women was reported for a large epidemiological study [76] and confirmed further by studies indicating that women with high levels of endogenous estrogen were less prone to develop AD [77]. However, HRT was found to be ineffective in preventing AD when administered in postmenopausal women aged over 65 years [78].

The mechanistic basis for HRT in AD remains to be resolved, although progress is being made. Notable in this regard, a novel therapy that uses leuprolide acetate, a gonadotropin-releasing hormone (GnRH) agonist that suppresses production of luteinizing hormone by downregulating pituitary GnRH receptors, is currently being studied with encouraging results [79–81].

## 7 CELL CYCLE

Primary neurons in the normal brain are viewed as being quiescent and in $G_0$. However, in AD, multiple lines of evidence suggest that neurons vulnerable to degeneration emerge from this postmitotic state—phenotypically suggestive of cells that are cycling, rather than the normal terminally differentiated nondividing state [10, 82–101]. The successful duplication of deoxyribonucleic acid (DNA) [102] shows that neurons successfully complete S phase and precludes the possibility that the re-expression of various cell cycle markers is an epiphenomena. However, while various mitotic markers are upregulated in vulnerable neurons in AD, no evidence of actual mitosis has ever been found. Given this lack of evidence for successful completion of the cell cycle, it is likely that the reactivation of cell cycle machinery in postmitotic neurons leads to their death. The cell cycle may, therefore, represent a novel approach to the treatment of AD [103, 104].

## 8 PHOSPHORYLATED TAU

Abnormally phosphorylated tau is the major protein component of neurofibrillary tangles, the first lesion to be characterized and associated with AD. Hyperphosphorylation causes disengagement of tau from microtubules and aggregation of the filamentous protein. [105]. Importantly, hyperphosphorylated tau (phospho-tau), which accumulates into paired helical filaments/neurofibrillary tangles, is not toxic to the neuron and does not induce the apoptotic cascade, and as much as 40% of phospho-tau is not aggregated into neurofibrillary tangles [106]. Pathologically active phospho-tau does not bind tubulin but instead sequesters normal tau in addition to other microtubule-associated proteins, which interrupts assembly and disassembly of normal microtubules [107, 108]. Tau is the substrate for a number of kinases, such as glycogen synthase kinase 3 (GSK3), cyclin-dependent protein kinase 5, and protein kinase A [109]. Dephosphorylation of phospho-tau protein has been shown in vivo by alkaline phosphatase, protein phosphatase 2A (PP-2A), PP-2B, and PP-1, all of which convert it into a normal state lacking toxic properties [110, 111]. PP-2A and PP-1 are responsible for 90% of the serine/threonine protein phosphatase activity in mammalian cells [112]. Activities of PP-2A and PP-1 have been shown to be compromised in AD [110, 113], indicating that insufficient dephosphorylation could be responsible for the appearance of phospho-tau. These mechanisms for aberrant accumulation of phospho-tau generate a number of novel therapeutic targets, currently in the initial stages of design and testing. For instance, restoring PP-2A activity by repressing PP-2A inhibitors, or inhibiting the activity of the kinases that phosphorylate tau, will prevent abnormal phosphorylation from occurring. A second strategy involves preventing the ability of phospho-tau to sequester normal tau, allowing normal function of other microtubule-associated proteins, thus preserving cellular integrity. Drug designs capable of achieving these goals are still in the early stages of development. High-throughput assays that are capable of measuring antisequestering effects are being addressed by researchers in the field [114].

## 9 EXCITOTOXICITY

Almost all neurons of the CNS carry the *N*-methyl-D-aspartate subtype of ionotrophic L-glutamate receptors. These receptors mediate postsynaptic influx of $Ca^{2+}$ after neurotransmission. It is theorized that excitotoxicity, resulting from excessive activation of these receptors, increases the vulnerability of CNS neurons, leading to neuronal degeneration characteristic of the development of AD.

In one school of thought, clinical manifestations early in the disease are the result of synaptic failure [31], while disease severity is the result of synaptic loss [115]. Memantine, the most recently approved drug for AD treatment, prevents pathological excitotoxicity at the

synapse and is believed to preserve physiological activation [116–118].

Early pathological changes in AD apparently occur in the medial temporal lobe, including the transentorhinal allocortex [119] and hippocampal formation. Neocortical glutamatergic neurons in layers III and IV are also vulnerable [120]. Excitatory amino acids, such as L-gluamate (L-Glu), are among the neurotransmitters used by these cells, although L-Glu distribution within the CNS is extensive. At basal conditions, the concentration of L-Glu in the synaptic cleft is around 0.6 $\mu M$ [121], while synaptic transmission allows for a localized rise to 10 $\mu M$ within the synaptic cleft [122]. Termination of excitation occurs by high-affinity reuptake on both pre- and postsynaptic neuronal cell membranes and the membranes of adjacent glial cells [123]. When uptake mechanisms are impaired, excitatory amino acids cause selective neuronal toxicity, through N-methyl-D-aspartic acid (NMDA)-mediated $Ca^{2+}$ influx [124].

A potentially important role of astrocytes is apparent in their intrinsic function to convert glutamate to glutamine by glutamine synthetase. Glutamine is then released by astrocytes and taken up by neurons where it is converted to glutamate in the mitochondria by the mitochondrial glutaminase. Recent studies have shown that glutamine synthetase is oxidized in the brains of individuals with AD [125]. This may explain the reported decrease in the activity of glutamine synthetase in AD patients [126]. While antioxidants may prove to be effective at preventing pathological oxidation, one therapy thought to block excitotoxicity through interaction with membrane receptors was also developed. Memantine is a blocker of glutamate-gated NMDA channels [127] and has become a popular therapy in recent years.

Memantine is thought to prevent excitotoxicity mediated by glutamate-gated NMDA receptors by blocking pathological activation. This property has been shown to occur due to the rapid, voltage-dependent interaction between memantine and the NMDA receptor channel [128]. Memantine blocks the receptor channel under normal physiological conditions and leaves the receptor channel upon activation. Additionally, memantine remains in the channel during pathological activation, preventing excitotoxicity and allowing for normal activation and memory formation. In animal models, memantine has been shown to prevent excitotoxic activation of glutamate receptors and preserve their physiological activation [116, 117, 129]. Clinical safety has been thoroughly studied in subjects diagnosed with mild to moderate dementia [130, 131], demonstrating significant improvements in psychopathological performance and behavior. Additional studies in a severely demented population [132] found that memantine treatment significantly improved the functional capabilities of these patients.

## 10 CHOLINERGIC DEFICITS

AD can be characterized as a deficit in cholinergic neurotransmission due to loss of cholinergic neurons of the basal nucleus of Meynert [133]. Evidence has demonstrated that the enzymes involved in synthesis [choline acetyltransferase (ChAT)] and degradation [acetylcholinesterase (AChE)] have reduced activity and may be responsible for this deficit [134, 135]. In light of this neurotransmitter deficiency, strategies to boost the level of acetylcholine have been developed for the treatment of AD. This has lead to the development of AChE inhibitors (AChEIs) that prevent the breakdown of the neurotransmitter inside the synaptic cleft. The first drug approved for the treatment of AD in 1993 was 1,2,3,4-tetrahydro-9-aminoacridine (tacrine) [136]. Currently, three other AChEIs are available on the market from different manufacturers. The second generation of drugs has proven to be more clinically effective and produce less severe side effects than the first generation. These drugs are currently prescribed for patients with mild to moderate progression of AD under the following names: Donepezil (Eisai Company and Pfizer Inc.), ENA-713 (Novartis Pharmaceuticals), and Galantamine (Hoechst Marion Roussel Inc., Shire Pharmaceutical Group, and Janssen Pharmaceutical).

Cholinergic therapy is considered a short-term intervention for the symptomatic treatment of AD. The effect of these inhibitors is to cognitively stabilize 50% of patients in treatment for 1 year. Clinical studies have indicated that beneficial effects can be maintained up to 36 months [137–139]. The stabilization of cognitive decline has lead researchers to investigate whether AChEIs can affect the amyloid cascade or the neurotoxicity associated with Aβ [140].

Cholinesterase inhibitors are currently being investigated to find additional benefits such as delay of onset and time of efficacy. To test these criteria, research has moved from AD patients to patients with mild cognitive impairment (MCI) [141]. MCI patients are identified due to their high risk of developing dementia. Two major studies are underway in the United States and Europe to address cholinesterase inhibitor use in populations of MCI patients [142].

Long-term stabilization that can occur when AD patients are treated with AChEI therapy has been associated with the ability of AChEI to affect AβPP metabolism [137]. Evidence has been published showing that AChEIs increase secretion of AβPP, thus slowing down the production of Aβ peptide and amyloidogenic com-

pounds [143, 144]. This suggests that AChEI could be administered at much earlier preclinical stages in at-risk individuals, and that combinatorial therapies represent future alternatives to AChEI monotreatment [137].

Neurotropins are currently being investigated as treatments to supplement the other therapeutic targets addressed. Neurotropins are of particular interest due to their ability to upregulate functions of cholinergic neurons [145]. Evidence has shown that neurotropins share the same signaling pathways as Aβ pathways mediating toxicity in neurons [146, 147]. Aβ has been found to bind to the p75 neurotropin receptor ($p75^{NTR}$), which causes $p75^{NTR}$-mediated cell death [148]. A precursor of nerve growth factor, proNGF, has been associated with signaling through $p75^{NTR}$ [149]. Research concerning proNGF in AD patients has shown the levels are increased in the brain [150].

Neurotropins are difficult to deliver effectively due to the short half-lives, on the order of minutes, significantly hampering the ability of these compounds to reach the central nervous system [151]. Additionally, neurotropins affect a broad range of biological signals, including sprouting of sympathetic nerves and upregulation of pain mechanisms. The development of neurotropin mimetics, altering only a subset of signaling cascades, is a partial answer to these side effects.

Investigations of NGF interaction with $p75^{NTR}$ have shown that regulation of different intracellular effector molecules occurs upon binding [147, 152]. Studies concerning peptidomimetics corresponding to specific regions of NGF have shown that their effects can occur via $p75^{NTR}$-dependent mechanisms to prevent neuronal death. These studies have included NGF peptidomimetics corresponding to loops 1 and 4 of NGF globular protein, both preventing neuronal death mechanisms via $p75^{NTR}$ receptor [153–155]. Recent findings have shown that a number of adaptor proteins are involved in the survival and death signaling mediated via $p75^{NTR}$ [156–158]. An interesting finding concerning these adaptors is that the selection of an adaptor is regulated by the nature of the ligand, which suggests that peptidomimetics may be able to regulate adaptor proteins [159]. These findings provide further support that peptidomimetics could possibly trigger $p75^{NTR}$ signaling in a manner to prevent cell death in AD patients.

## 11 CONCLUSION

Sporadic AD is a complex process that develops over decades and involves biochemical dysfunction in multiple arenas. While Aβ and tau are attractive targets for therapy, both accumulate as late phenomena in the disease process, particularly in sporadic disease. The lack of specificity of plaques and tangles for AD, particularly in early and intermediate stages of the disease, and with advanced age, highlight the need to look beyond Aβ and tau for early pathogenic factors and treatment. Indeed, one school of thought is that Aβ and tau are protective adaptations to disease. Oxidative stress and cell cycle alteration, for example, are known to predate clinical symptoms and pathological accumulations of Aβ and tau. Moreover, the strides that have been made in lipid metabolism with statins, and in neuroprotection from anti-inflammatory treatment, as well as antiexcitotoxic and cholinergic treatment, emphasize the point that AD is complex and that any one strategy or construct may not be sufficient [10]. As knowledge expands, the list of avenues for treatment will only expand, and an open-minded approach to treatment will be all the more necessary.

## ACKNOWLEDGMENTS

We thank Margaret Hampton for title inspiration. Margaret, and her husband Al, caregiver and patient, respectively, represent two out of the many millions touched by this devastating disease and to whom this work is dedicated.

Work in the authors' laboratories is supported by the National Institutes of Health and the Alzheimer's Association.

# NEUROTROPHIC FACTORS AS NOVEL THERAPEUTIC TARGETS

Stephen D. Skaper

*Neurosciences Centre of Excellence for Drug Discovery, GlaxoSmithKline Research and Development Limited, Essex, United Kingdom*

## 1 INTRODUCTION

In mammals and other vertebrates, soluble peptide growth factors play essential roles in intercellular communication. They exert their effects by signaling through surface membrane receptors that interact with diverse types of intracellular second-messenger systems. In a sometimes surprising manner, many growth factors have been found to subserve a wide variety of functions by acting on many cell types at different stages of development or in adult life. One of the major advances of cellular neuroscience has been to recognize that much of the cellular damage resulting from such central nervous system (CNS) insults as stroke, trauma, and neurodegenerative disease may be caused by a limited number of endogenously generated molecules with neurotoxic activities. Less well developed is the idea that endogenous mechanisms exist to provide neuroprotection and that endogenous molecules may be produced specifically to service neuroprotective signaling functions.

Neurotrophic factors are secreted proteins that promote neurite outgrowth, neuronal cell differentiation, and survival both in vivo and in vitro. Since their discovery in the 1950s, neurotrophic factors have raised expectations that their clinical application to neurodegenerative diseases might provide an effective therapy for what are now untreatable conditions. There is a large volume of evidence for neuroprotective effects of neurotrophic factors in animal models of neurodegerative diseases. These applications include abolishing cell loss in the septum following fimbria-fornix transection, a cholinergic model for Alzheimer's disease [1, 2], recovery from chemically induced parkinsonism [3, 4], motor neuron disease [5, 6], and spinal cord injury [7–9]. While showing great promise for the treatment of such dirorders, the poor pharmacokinetics and bioavailability of these protein factors have limited the use of polypeptides as drugs. The development of nonpeptidyl small-molecule neurotrophic factor mimetics would obviate the need for protein factors and the potential problems associated with them. This chapter will discuss various strategies whereby a small molecule can influence neurotrophic signaling.

## 2 NEUROTROPHINS AND THEIR RECEPTORS

Neurotrophins were identified as promoters of neuronal survival, but it is appreciated that they regulate many aspects of neuronal development and function, including synapse formation and synaptic plasticity [10–13]. The first neurotrophin, nerve growth factor (NGF), was discovered during a search for survival factors that could explain the deleterious effects of deletion of target tissues on the subsequent survival of motor and sensory neurons [14]. NGF is part of the neurotrophin

family of approximately 25-kDa polypeptides that function as homodimers, and that share a high degree of structural homology and includes brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4) [15]. Neurotrophins are found in both mammals and lower vertebrates, while the neurotrophin homologs NT-6 and NT-7 were cloned in fish [16, 17].

The neurotrophins interact with two entirely distinct classes of receptors, Trks (tropomyosin receptor kinases) and $p75^{NTR}$ [neurotrophin receptor (NTR)], the first discovered member of the tumor necrosis factor receptor superfamily. The former was initially identified as a low-affinity receptor for NGF but was subsequently shown to bind each of the neurotrophins with approximately equal nanomolar affinity [18, 19] but lacks a catalytic motif. $p75^{NTR}$ binds NGF along the interface between two NGF monomers, and binding results in a conformational change in NGF that alters the monomeric interface on the opposite side of the NGF dimer, eliminating the potential for binding of one NGF dimer to two $p75^{NTR}$ monomers. In contrast to interactions with $p75^{NTR}$, the neurotrophins dimerise the Trk receptors, resulting in activation through transphosphorylation of the kinases present in their cytoplasmic domains. The four neurotrophins exhibit specificity in their interactions with the three members of this receptor family with NGF activating TrkA, BDNF and NT-4 activating TrkB, and NT-3 activating TrkC. In addition, NT-3 can activate the other Trk receptors with less efficiency (Fig. 1). In vitro studies indicate that the presence of $p75^{NTR}$ potentiates activation of TrkA by suboptimal concentrations of NGF, although it does not appear to potentiate the activation of other Trk receptors similarly by their ligands [20, 21], and that $p75^{NTR}$ collaborates with TrkA to form high-affinity ($10^{-11}$ *M*) binding sites for NGF [22]. The major site at which neurotrophins interact with the Trk receptors is in the membrane-proximal immunoglobulin (Ig)-like domain. The three-dimensional structures of the domain in each of the Trk receptors have been solved [23]. In addition, the structure of NGF bound to the TrkA Ig domain has also been determined [24]. These results have made it possible to identify residues in the neurotrophins and the Trk receptors that account for the specificity observed in their interactions [25, 26]. Such information may prove useful in the design of small-molecule mimetic ligands for neurotrophin receptors, as will be discussed in a later section.

Through Trk receptors, neurotrophins activate Ras, phosphatidyl inositol-3 kinase, phospholipase C-γ1, and signaling pathways controlled through these proteins, such as mitogen-activated protein kinases. Activation of $p75^{NTR}$ results in activation of the nuclear factor-κB and Jun kinase as well as other signaling pathways. Several excellent reviews describe recent progress in understanding the signaling pathways stimulated by the neurotrophins that affect the survival, differentiation, and function of cells within the nervous system [10–13].

**Figure 1** Neurotrophins and their receptors. The neurotrophins display specific interactions with the three Trk receptors: NGF binds TrkA, BDNF and NT-4 bind TrkB, and NT-3 binds TrkC. In some cellular contexts, NT-3 can also activate TrkA and TrkB albeit with less efficiency. All neurotrophins bind to and activate $p75^{NTR}$. CR1–CR4, cysteine-rich motifs; C1/C2, cysteine-rich clusters; LRR1–3, leucine-rich repeats; Ig1/Ig2, immunoglobulin-like domains.

## 3 NEUROTROPHIC PROTEINS AS THERAPEUTIC AGENTS

The power of neurotrophic factors to regulate neuronal cell survival in the developing nervous system and to promote survival after injury or protect neurons in toxin-mediated disease models in animals has spurred the idea that such proteins could be harnessed for the treatment of neurodegenerative disease. For example, the traditional perspective of applying neurotrophins in the context of Alzheimer's disease is based on the premise that neurotrophins are capable of upregulating cholinergic function and of rendering neurons less vulnerable to certain processes causing degeneration [1, 2]. Another case is that of glial cell-line-derived neurotrophic factor (GDNF), which acts on dopaminergic neurons. Administered intracerebrally, GNDF has neuroprotective and neurorestorative effects in toxin-induced rodent and nonhuman primate models of Parkinson's disease [3, 27, 28]. In spite of such encouraging preclinical data, clinical studies have proven largely disappointing. Neurotrophic proteins have failed to show a beneficial effect in human trials of amytrophic lateral sclerosis [29–33], and in some cases the side effects were severe [34, 35]. A negative outcome was also reported for randomized, controlled trials of GDNF in Parkinson's disease patients [36, 37]. Neurotrophic factor treatment of CNS diseases presents an especially complex problem since these polypeptides have poor pharmacokinetics and bioavailability and are not able to cross the blood–brain barrier. Neurotrophic proteins can be modified to increase blood–brain barrier transport [38], and recent studies have shown that intravenous administration of BDNF, conjugated to an antitransferrin antibody, is able to traverse the blood–brain barrier in rats and provide neuroprotection in focal transient brain ischemia [39, 40]. Toxicology studies in primates showing cerebellar degeneration following the administration and subsequent withdrawal of high doses of GDNF raise concerns about dosing and targeting of delivery. Viral vector or cell-based gene therapy approaches may prove more advantageous for the targeted delivery of lower doses of neurotrophic factors. Dopaminergic neuroprotection by viral-mediated delivery or GDNF or the GDNF-related factor neurturin [41] has been demonstrated in animals [3, 42, 43]. In the case of spinal cord injury, the transplantation of genetically modified cells (e.g., viral expression of neurotrophins either in vivo or ex vivo in stem cells) to lesion sites has been investigated as a means to augment axonal regeneration [44–46]. A cell-based approach for NGF delivery has shown promise in a phase I trial in Alzheimer's disease [47].

Peripheral nervous system (PNS) disorders might be more amenable to a neurotrophic protein therapeutic. NGF, which is selectively trophic for small fiber sensory and sympathetic neurons, was selected as a potential therapy for diabetic polyneuropathy because of the serious consequences associated with degeneration of those neuronal populations in this condition. In addition, a reduced NGF availability may contribute to the pathogenesis of diabetic neuropathy [48, 49], and animal models of neuropathy respond to the exogenous administration of NGF [50]. Two sets of phase II clinical trials suggested that recombinant human NGF (rhNGF) administration was effective in ameliorating the symptoms associated with both diabetic polyneuropathy [51] and human immunodeficiency virus (HIV)-related neuropathy [52]. These early studies, however, revealed that painful side effects were dose limiting for NGF. A large-scale phase III clinical trial of 1019 patients randomized to receive either rhNGF or placebo for 48 weeks failed to confirm the earlier indications of efficacy [53]. Such side effects are not surprising, as increased NGF content in peripheral tissues can cause inappropriate axonal sprouting [54] and hyperalgesia [55].Other protein factors with peripheral nerve regeneration activity are efficacious in experimental diabetic neuropathy and include sonic hedgehog protein [56] and ciliary neurotrophic factor [57]. Whether or not the latter would produce the desired trophic effects of NGF in humans without causing hyperalgesia remains to be investigated.

## 4 FUNCTIONAL MIMETICS OF NEUROTROPHINS ACTING AT TRK RECEPTORS

Despite the therapeutic potential of neurotrophic proteins, there are inherent drawbacks with the use of polypeptides applied as drugs: in vivo instability; unsuccessful tissue targeting; pleiotrophic effects due to binding multiple receptors and co-receptors, and activation of multiple pathways that were not intentionally targeted; and relatively high production cost for medicinal applications. Such problems may be averted by developing highly selective receptor ligands, with chemical and pharmacological properties such as proteolytic stability, small size, ability to penetrate tissue barriers, and ability to agonize or antagonize the receptors. The pharmacological advantages of mimetics over protein therapeutics are well documented and include lack of immunogenicity, low molecular mass, low manufacturing costs, and good pharmacokinetic profiles [58].

The first rationally designed TrkA agonists were based on the use of ligand mimicry and antibody

mimicry strategies [58, 59] to generate peptide analogs of two agonists directed to the extracellular domain of TrkA: the peptide sequence of NGF itself [60–62] and the anti-TrkA monoclonal antibody (mAb) 5C3 [63]. This antibody most likely acts through its two variable domains to physically join together two Trk monomers. TrkA binding is mediated by a discrete β-turn region (amino acid residues 92–97) of these ligands, since crystallized peptides and peptidomimetic compounds incorporating these residues were found to activate TrkA and demonstrate neurotrophic effects in cell-based models [64–66]. Such cyclic peptide dimeric ligands may act as TrkA partial agonists, inducing receptor dimerization, phosphorylation, and and internalization [64]. Other conformers or linear peptides were inactive. In fact, most monomer cyclic peptide β-turn mimetics of NGF and BDNF are reported to have only antagonistic properties, inhibiting neurotrophin binding and activity [60, 67]. Similar findings show that a dimeric (but not monomeric) cyclized version of amino acids 92–96 of NGF also acts as a partial TrkA agonist, with neurotrophic effects being blocked by TrkA inhibitors [65].

Based on the pharmacophores of the mAb 5C3 and NGF peptide analogs described above, a focused β-turn peptidomimetic library of ~60 compounds was synthesized, leading to the identification of D3 [66], a small, selective, and proteolytically stable agonist of the TrkA receptor (Fig. 2). A similar compound, C59, lacked neurotrophic effects. These results indicate that a small β-turn peptidomimetic can activate a tyrosine kinase neurotrophin receptor that normally binds a relatively large protein ligand. Although D3 is still far short of an NGF mimetic in terms of its potency, treatment of cognitively impaired aged rats with D3 has been shown to act as a neuroprotective agent. Aged rats showed improved memory and improved cholinergic phenotype. The effect was long-lived, for 3 months after drug delivery. D3 performed equally or better than NGF [68].

Crystallographic and molecular modeling studies of NGF/TrkA complexes [24, 25, 69, 70], site-directed mutagenesis [71–75], and results from chemical modification of amino acid residues [70, 76] have identified loops 1 and 4 and the N-terminal region of NGF as the most relevant for its biological activity. Among various peptides reported in the literature, linear peptides showed inhibitory, but no agonist, activity [77], and, as mentioned above, cyclic peptides corresponding to the loop 1 sequence were shown later to have a 10-fold higher inhibitory activity [60]. The first NGF loop domain peptides described to have neurotrophic activity were the loop 1 homodimer mimetics reported by Longo et al. [78]; loop 4 mimetics with agonist activity appeared several years later [64–66]. The low efficacy of these compounds led Colangelo and colleagues [79] to use a different approach based on the combination of different NGF regions in the same molecule. Linking both the L1 and L4 loops together with an appropriate spacer, with or without the N-terminal region, produced peptides (NL1L4 and L1L4) that induced differentiation of dorsal root ganglion neurons and stimulated tyrosine phosphorylation of TrkA but not TrkB. In addition, L1L4 was able to induce differentiation of PC12 cells, with an $EC_{50}$ (1 μ*M*) well below the range of concentrations reported for the more active homopeptides [65, 78]. More interestingly, the L1L4 peptide reduced neuropathic behavior and restored neuronal function in a rat model of peripheral neuropathic pain, thereby suggesting a potential therapeutic role for this NGF-mimetic peptide [79].

**Figure 2** Structures of D3, D3-biotin, and C59. (Reproduced from ref. 66, Fig. 1. Copyright 2000, with permission from the American Society for Pharmacology and Experimental Therapeutics.)

Small, dimeric peptides designed to mimic a pair of solvent-exposed loops important for the binding and activation of the BDNF receptor, TrkB, have been described [80]. The monomer components that make the dimers were based on a monocyclic monomeric peptide mimic of a single loop of BDNF (loop 2) shown previously to be an inhibitor of BDNF-mediated neuronal cell survival [81]. These bicyclic dimeric peptides behaved as partial agonists with respect to BDNF, promoting sensory neuron survival in vitro. A highly conformationally constrained tricyclic dimeric peptide was then synthesized in which the monomeric subunits were linked by two dimerizing linkages. Although the tricyclic dimer was still a partial BDNF agonist, it was 10-fold more potent in its neuronal survival effect than the best of the bicyclic dimers, making it ~2-fold less potent than BDNF itself. Partial agonistic behavior could result from the compound being less efficient than BDNF in bringing about dimerization of BDNF or because of inappropriate conformational flexibility of the dimerizing linkages (although the retention of partial agonism by the highly constrained tricyclic compound would argue against this). A consequence of reduced dimerization efficiency could be a reduced ability to cause the autophosphorylation of the five tyrosine residues in TrkB (resulting in reduced activation of downstream signaling pathways). An alternative mechanism for the partial agonist behavior of the dimeric peptides is that they act through TrkB only, even as full TrkB agonists, and not $p75^{NTR}$. A series of dimeric β-turn mimetics that act as agonists of TrkC have recently been described [82] (Fig. 3), as well as a tandem repeat cyclic peptide agonist of TrkB [83].

Additional examples of dimeric peptides able to mimic the effects of larger protein agonists, presumably by being able to bring about receptor dimerization include agonists of the cell adhesion molecule N-cadherin. In the nervous system, N-cadherin function has been implicated in cell migration, axonal growth and guidance, and synapse formation and synaptic plasticity [84]. Peptide mimetics of two linear sequences from extracellular domain 1 (HAVDI and INPISGQ) of N-cadherin function as highly specific antagonists [85], while cyclic peptides containing a tandem repeat of the individual motifs function as N-cadherin agonists that stimulate neurite outgrowth in a similar manner to native N-cadherin [86]. The cyclic peptide N-Ac-*CHAVDINGHAVDIC*-$NH_2$ (SW4) containing the HAVDI sequence in tandem was efficacious also in promoting the in vitro survival of several populations of CNS neurons in paradigms where fibroblast growth factor-2 (FGF-2) is effective [87] (Fig. 4). The neuroprotective effects of SW4 displayed a concentration dependence similar to those inducing neuritogenesis and were inhibited by a monomeric version of the same motif and by a specific fibroblast growth factor (FGF) receptor antagonist. These data suggest that SW4 functions by binding to and clustering N-cadherin in neurons and thereby activating an N-cadherin/FGF signaling cascade,

**Figure 4** The Dimeric HAVDI peptide SW4 attenuates glutamate-induced toxicity in culture hippocampal neurons. Cultures (days in vitro 7–9) were pretreated with the indicated concentrations of SW4 peptide for 48 h and then exposed to 50 μ*M* glutamate, and neuronal survival was quantified 24 h later by a colourimetric reaction (MTT). Data are means ± SD (three experiments) expressed relative to no glutamate (100%). $^{*}P < 0.05$ or $^{\#}P < 0.01$ vs. glutamate only. (Reprinted from ref. 87, Fig. 3. consistent with the ability of cell adhesion molecules to activate and FGF receptor-signaling cascade in growth cones [88].

## 5 TARGETING THE P75$^{NTR}$ AS A STRATEGY TO PROMOTE NEURON SURVIVAL

Specific effects of neurotrophins depend on whether signaling is activated via a member of the Trk receptor tyrosine kinase family or the p75 neurotrophin receptor p75$^{NTR}$. In contrast to the Trk receptors, the function of p75$^{NTR}$ remains enigmatic, although it participates in multiple cellular activities apparently by functioning as a co-receptor with different partners [11, 89]. In the absence of a co-expressed Trk receptor, p75$^{NTR}$ can mediate death in neurons [90, 91] and oligodendrocytes [92]. p75$^{NTR}$ can be activated selectively by proneurotrophins [93], which are potent inducers of p75$^{NTR}$-mediated cell death [94, 95] attributable to concomitant interaction with the sorting receptor sortilin [96]. Pro-NGF induces death of oligodendrocytes after spinal cord injury [94] and cortical neurons after injury [95]. Pro-NGF is also abundant in the Alzheimer brain [97], raising the possibility that this form of NGF may contribute to death of septal cholinergic neurons via activation of p75$^{NTR}$-mediated apoptosis. Indeed, a recent study has shown that pro-NGF produced in the brain under pathological conditions can elicit apoptosis in basal forebrain neurons in vitro [98].

Studies showing that neurotrophin binding to p75$^{NTR}$ can promote cell survival in the absence of Trk receptors [99, 100], together with recent structural data indicating that NGF may bind to p75$^{NTR}$ in a monovalent manner [101], raise the possibility that small molecules mimicking a single p75$^{NTR}$-interacting domain of NGF might be capable of competing with NGF or pro-NGF binding and/or modifying p75$^{NTR}$ signaling and positively regulate cell survival. A pharmacophore designed to capture selected structural and physicochemical features of a neurotrophin domain (β-hairpin loop 1) known to interact with p75$^{NTR}$ was applied to in silico screening of small-molecule libraries. Four of 23 compounds selected showed neurotrophic activity for cultured sensory neurons (Fig. 5) [102] and promoted survival of CNS neurons while inhibiting pro-NGF-mediated death of mature oligodendrocytes [103]. Compound LM11A-24 prevented p75$^{NTR}$-dependent motor neuron death induced by either exogenous addition of NGF or by NGF-producing reactive astrocytes in co-culture conditions [104]. Increased levels of NGF and p75$^{NTR}$ re-expression have been implicated in motor neuron death following axotomy [105] and in motor neuron disease models [106, 107]. Targeted modulation of

**Figure 5** LM11A compound structures. (Reproduced from ref. 103, Fig. 2. Copyright 2006, with permission from The Society for Neuroscience.)

p75$^{NTR}$ signaling may constitute a strategy for therapeutic development.

Alzheimer's disease is characterized by the accumulation of neurotoxic amyloidogenic peptide Aβ and progressive impairment of cognitive function, particularly memory [108]. As mentioned above, it has been proposed that increased levels of proneurotrophins, such as occur in Alzheimer's disease, may underlie degeneration of the cholinergic innervation to the hippocampus (the septohippocampal pathway) via p75$^{NTR}$ activation. However, it is also possible that Aβ could be directly responsible for activating p75$^{NTR}$-mediated cell death in Alzheimer's disease, given that it is a ligand for the receptor [109] and can stimulate p75$^{NTR}$-mediated cell death signaling cascades in cell lines [110, 111]. Like the amyloid precursor protein, the extracellular domain of p75$^{NTR}$ is cleaved by a metalloprotease, generating a transmembrane-linked C-terminal fragment. This is

then cleaved by a γ-secretase, liberating a soluble intracellular domain [112]. Ligand binding can initiate this process, and both fragments of $p75^{NTR}$ have been shown to mediate death signaling [113–116]. A new study has now provided evidence of a direct link between $p75^{NTR}$ signaling and Aβ-induced toxicity in hippocampal neurons in vitro and in cholinergic basal forebrain neurons in vivo [117]. Neuronal death correlated with $A\beta_{1-42}$ peptide-stimulated accumulation of the constitutively active death-signaling $p75^{NTR}$ C-terminal fragment generated by inhibition of γ-secretase activity [117]. These results provide a novel mechanism to explain the early and characteristic degeneration of the septohippocampal pathway that occurs in Alzheimer's disease.

Agonist monoclonal antibodies [118] or peptide mimetics [83], which activate TrkB without binding to $p75^{NTR}$ at all, represent a potential alternative strategy to the deleterious consequences of $p75^{NTR}$ activation. These molecules demonstrate neurotrophic activity [83, 118] and promote neurite growth in the presence of a myelin inhibitor [118], for which $p75^{NTR}$ serves as the signaling component [119]. Thus, agents that activate Trk receptors in the absence of $p75^{NTR}$ binding, or that inhibit neurotrophin/$p75^{NTR}$ binding, might be more effective than neurotrophins at promoting repair.

## 6 SMALL-MOLECULE NONPEPTIDE NEUROTROPHIN RECEPTOR AGONISTS

Asterriquinones are naturally occurring bis-indolyl-dihydroxyquinones that activate tyrosine kinase receptors. They were originally identified as activators of the insulin receptor [120, 121]. The molecules are small and readily cell permeable, and they act directly on the receptor tyrosine kinase domain, although the mechanism is not known [120]. Utilizing a natural product screen, a small-molecule nonpeptidyl fungal metabolite isolated from *Pseudomassaria*, L-783,281 was initially identified as an activator of the insulin receptor [120] (Fig. 6). The original compound demethylasterriquinone-B1 (DAQ-B1, or L-783,281) crossed the blood–brain barrier and, in a separate study, was shown to be efficacious at low micromolar concentrations in stimulating TrkA, B, and C phosphorylation to various extents in CHO cell lines stably expressing human Trk receptors, although it was toxic to neurons [122]. L-783,281 also stimulated Trk phosphorylation in a number of rat and human primary neuronal cell cultures, whereas the highly similar compound, L-767,827 was without effect [122]. Mechanistic studies suggested that L-783,281 probably causes receptor dimerization and transphosphorylation by binding in a noncovalent

**Figure 6** The structures of L-783,281 and L-767,827. (Reproduced from ref. 122, Fig. 1. Copyright 2001, with permission of Blackwell Publishing.)

manner. Unfortunately, cytotoxicity of L-783,281 precluded evaluating effects on neuronal cell survival and neurite outgrowth. In a more recent study, combinatorial libraries of asterriquinones (>300) and mono-indolyl-quinones (>60) were screened using a 96-well enzyme-linked immunosorbent assay that detects phosphorylated TrkA [123]. The libraries were also screened for cytotoxicity. From these screens, the authors generated quantitative structure–activity relationship models for activity and toxicity, culminating in the selection of two compounds, 2-(6-chloro-1*H*-indol-3-yl)-5-(2-cyclopropyl-1*H*-indol-3-yl)-3,6-dihydroxy-[1,4]-benzoquinone (1H5) and 2,5-dimethoxy-3-(7-fluoro-1*H*-indol-3-yl)-[1,4]-benzoquinone (5E5), for further study based on high activity and low cytotoxicity. Compound 1H5 (30 μ*M*) is an asterriquinone that is a moderate TrkA activator (50% of the activity of 100 ng/mL NGF), and it shows little toxicity at concentrations up to 100 μ*M*. 1H5 can protect terminally differentiated PC12 cells from apoptotic cell death induced by NGF withdrawal [123]. Compound 5E5 (30 μ*M*) is a mono-indolyl-quinone that is a very strong activator of TrkA (>200% the activity of 100 ng/mL NGF), and it is non-toxic up to 10 μ*M*. Activation of TrkA could be detected at 1 μ*M* 5E5, and 3–10 μ*M* 5E5-activated TrkA and extracellular signal-regulated kinase as strongly as a maximal concentration of NGF (100 ng/mL) [123]. Moreover, a low concentration of 5E5 (1 μ*M*) combined with a submaximal concentration of NGF (10 ng/mL) promoted neuronal-like differentiation of PC12 cells. As the mitogen-activated protein kinase (MAPK) pathway is essential for NGF-induced neuritogenesis [124, 125], this may explain why 5E5 was better at stimulating differentiation than promoting survival, because 5E5 is a potent activator of extracellular signal-regulated kinase but a weaker activator of Akt (protein kinase B). The phosphatidylinositol 3-kinase/Akt signaling pathway contributes more than the MAPK pathway in neuronal survival [126, 127]. Although 1H5 and 5E5

themselves are unsuitable as drug candidates, they provide lead compounds that can be applied to preclinical models of neurodegeneration for proof-of-principle experiments.

Another approach to target Trk receptor activation may be that of identifying agents that increase the activation of Trk receptors in the co-presence of (sub) threshold concentrations of neurotrophin. Historical evidence suggests that the monosialic acid ganglioside GM1, like the neurotrophins, has the potential to protect injured and aged CNS neurons, enhance neuronal phenotypic expression, induce neuronal sprouting, and enhance neuronal function and metabolism [128]. The pleiotropic neurotrophic activity of GM1 extends to a wide range of neuronal cell populations, suggesting an interaction with a wide spectrum of neurotrophic factors or common signaling pathways. Indeed, GM1 was shown to enhance NGF-induced TrkA activation and dimerization [126–132] and to potentiate the neurotrophic effect of NGF in vivo [133, 134]. GM1 added to brain slices activated extracellular-regulated protein kinases (Erks) in a Trk-sensitive manner, while intracerebroventricular administration of GM1 induced a transient phosphorylation of TrkA and Erk1/2 in hippocampus and striatum [135]. Both GM1 and its semisynthetic derivative LIGA20 activated TrkB and prevented glutamate-mediated apoptosis of cerebellar granule neurons, similar to BDNF [136]. The mechanism underlying the ganglioside actions have not been elucidated, and such compounds are not very brain penetrant.

K-252a and K-252b belong to a class of related indolocarbazoles of microbial origin that inhibit a range of kinases, including Trk [137, 138]. At concentrations below those that inhibit Trk activation, K-252b potentiates the stimulatory effect of NT-3 on TrkA phosphorylation and promotes peripheral sensory neuron survival and cholinergic neuron differentiation [138]. However, these compounds are not pharmacologically clean (e.g., non-Trk-related effects). Examination of a series of staurosporines led to the identification of a compound, L-753,000 (NB-506), that potentiated the action of NT-3 on TrkA (but not other Trks) and produced a range of neurotrophic effects at nanomolar concentrations without the kinase inhibitory response of K-252b [139] (Fig. 7). A compound structure similarity search of chemical libraries conducted based on the structures of L-753,000 and K-252b yielded several molecules that potentiated NT-3-mediated TrkB activation, exhibited no activity in the absence of neurotrophin, and did not potentiate receptor activation by NT-4 or BDNF. One such compound, BMS355249, was maximally effective at 100 n*M* in enhancing the effect of NT-3 at TrkA and TrkB and in potentiating NT-3-mediated cell survival [140]. Experiments using chimeric Trk receptors demonstrated that the extracellular domain was essential for compound potentiation and ruled out interaction with intracellular signaling molecules as a mechanism of compound activity [140].

**Figure 7** The Structure of L-753,000.

## 7 BDNF–SEROTONIN INTERACTIONS

BDNF and serotonin (5-hydroxytryptamine, 5-HT) are two seemingly distinct signaling systems that play regulatory roles in many neuronal functions, including survival, neurogenesis, and synaptic plasticity. A common feature of the two systems is their ability to regulate the development and plasticity of neural circuits involved in mood disorders such as depression and anxiety [141–143]. BDNF promotes the survival and morphological differentiation of 5-HT neurons both in culture and in vivo [144, 145]. Conversely, administration of antidepressant selective serotonin reuptake inhibitors enhances BDNF gene expression [146, 147]. The effect of antidepressants appears to be a general phenomenon, as pharmacologically diverse compounds, including inhibitors of monoamine transporters and metabolism, activate TrkB rapidly in the rodent anterior cingulate cortex and hippocampus [148]. Furthermore, acute and long-term antidepressant treatments induced TrkB-mediated activation of phospholipase-Cγ1 and increased the phosphorylation of cyclic adenosine monophosphate (CAMP)-related element binding protein, a major transcription factor mediating neuronal plasticity. Modulation of the phosphorylation of TrkB Shc binding site, phosphorylation of mitogen-activated protein kinase, or Akt by antidepressants was not observed [148]. Brain monoamines are crucial mediators of antidepressant-induced TrkB activation, as antidepressants did not produce TrkB activation in the brains of

serotonin- or norepinephrine-depleted mice. Rapid activation of the TrkB neurotrophin receptor and phospholipase-Cγ1 signaling thus seems to be a common mechanism for all antidepressant drugs and suggests that such molecules may serve as chemical templates for the design of TrkB modulators.

## 8 NEUROIMMUNOPHILINS

Immunophilins are a class of proteins best known for their key role in mediating the immunosuppressive actions of FK506 and cyclosporin A [149]. FK506 and FK506-derived inhibitors of the FK506-binding protein (FKBP)-type peptidylprolyl *cis/trans*-isomerases (PPIase) binds to an intracellular protein designated FKBP12. This FK506–FKBP12 complex binds to and inhibits the phosphatase calcineurin [150]. FKBP12 is highly expressed in the brain, and FK506 was found to promote neurite outgrowth in cell culture and to stimulate nerve regeneration following peripheral nerve injury [151], and to be neuroprotective in brain ischemia [152, 153]. The concentrations of FK506 required for neurotrophic activity also inhibit calcineurin, which can lead to suppression of immune function.

The adverse effects of FK506 have stimulated efforts to identify compounds with neurotrophic activity but lacking calcineurin inhibitory activity. The immunophilin ligand GPI1046 (Fig. 8) was reported to display neurotrophic actions and to stimulate structural and functional recovery in in vivo models of neurodegeneration [154–157] and to protect cultured dopaminergic neurons from toxicity by 1-methyl-4-phenylpyridine ($MPP^+$) and 6-hydroxydopamine (6-OHDA) [156–158] as well as promote dopaminergic function in 6-OHDA-lesioned rats [159]. More recent studies have shown GPI1046 to protect neurons from the lethal effects of human immunodeficiency virus-1 (HIV-1) proteins gp120 and Tat, by modulating endoplasmic reticulum calcium overload [160] and to induce selective expression of the astroglial glutamate transporter GLT1 in vitro and in vivo [161]. In the last study, treatment with GPI1046 protected motor neurons in an in vitro model of chronic excitotoxicity and prolonged the survival of transgenic mice with motor neuron disease [161]. V-10,367, an immunophilin ligand that binds to FKBP12 ($K_i = 0.5\,\mathrm{n}M$) (Fig. 8), and V-13,661, an immunophilin ligand that does not bind to FKBP12 ($K_i > 25\,\mathrm{m}M$), both protected against loss of dopaminergic terminals in the striatum following treatment with MPTP (*N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), which induces Parkinson-like symptoms in mice and primates [162]. V-10,367 was also protective in animals treated with a 6-OHDA lesion in the striatum. Both compounds promoted sprouting of intact neurons but did not increase survival of neurons in the substantia nigra. Other studies, however, have failed to demonstrate morphological protection of dopaminergic neurons in the substantia nigra by GPI1046 in MPTP-treated mice [163] or after 6-OHDA lesions [164]. One study testing GPI-1046 for behavioral and neuropathological changes following MPTP administration to monkeys found no evidence for a neuroprotective effect [165]. Taken together, the data on GPI1046 and V-10,367 suggest that these immunophilin ligands are able to elicit modest sprouting effects in vivo and in vitro, under certain conditions, but have no effect on neuronal cell survival.

**Figure 8** The Structures of GPI1046 and V-10,367.

The nature of the FKBP representing the primary target of these drugs remains enigmatic. Until now, 16 FKBPs have been identified in the human genome. There is increasing evidence to suggest that FKBP12 does not affect neuronal cell protection and regeneration. The peptidylprolyl isomerase (PPIase) activity targeted by active site-directed FKBP ligands, such as GPI1046, inhibit the calmodulin/$Ca^{2+}$-regulated FKBP38 with up to 80-fold higher affinity than FKBP12. The FKBP38-specific cycloheximide derivative, *N-(N′,N′*-dimethylcarboxamidomethyl)cycloheximide caused neuronal cell protection as well as neural stem cell proliferation in a rat model of transient focal cerebral ischemia [166]. These effects were still dominant when compound was applied 2–6 h postinsult. In parallel, sustained motor behavior deficits of injured rats were inproved by drug administration [166].

## 9 INHIBITION OF INTRACELLULAR SIGNALING PATHWAYS

Apoptosis has been proposed as a mechanism of cell death in Alzheimer's, Parkinson's, and Huntington's diseases and in amyotrophic lateral sclerosis. The stress-activated protein kinase or c-Jun N-terminal kinase (JNK) is a MAPK pathway activated in response to many extracellular stimuli and different forms of environmental stress (e.g., metabolic stress, radiation), including neurotrophic factor deprivation [167]. Staining with antibodies that recognize phosphorylated JNK

proteins reveals JNK activation in brain regions (cerebral cortex, hippocampus) affected by Alzheimer's disease pathology but not in unaffected regions or control brains [168, 169]. JNK activation has been observed also in brain specimens from patients with Parkinson's disease [170] and in midbrain dopaminergic neurons from MPTP-treated rodents [171]. MPTP-induced neurodegeneration and motor deficits were significantly reduced in JNK2/JNK3 knockout mice [172].

The MAPK pathway is organized as a cascade of at least three kinases: an MAPK kinase kinase (MAPKKK) first phosphorylates a dual-specificity protein kinase (MAPKK), which in turn phosphorylates the MAPK. The JNK pathway can be activated by small G-proteins, such as Cdc42 and Rac, members of the Rho family guanosine triphosphates (GTPases). In neurons, the mixed lineage kinase (MLK) family of kinases serves as the major MAPKKKs and phosphorylates the MAPK kinases 4 and 7 (MKK4 and MKK7), which in turn phosphorylate the JNKs [167]. Activation of the JNK pathway induces the expression of cell death genes (Fig. 9). Components of this pathway provide opportunities for pharmacological intervention and neuroprotection.

As discussed earlier, K-252a at high concentrations inhibits the survival-promoting effects of neurotrophins. In contrast, at low concentrations, K-252a on its own promotes survival and differentiation similar to the effects of neurotrophins [173, 174]. Compounds based on K-252a were synthesized to enhance the neurotrophic effects of K-252a while "dialing out" Trk inhibitory activity. A series of 3,9-bis[(alkylthio)methyl]- and bis(alkoxymethyl)-K-252a derivatives with reduced Trk inhibitory activity were identified, with 3,9-bis-[(ethylthio)methyl]-(8*R**,9*S**,11*S**)-(–)-9-hydroxy-9-methoxycarbonyl-8-methyl-2,3,9,10-tetrahydro-8,11-epoxy-1*H*,8*H*,11*H*,-2,7*b*,11*a*-triazadibenzo(*a,g*)cycloocta(*cde*)trinden-1-one] (CEP-1347 or KT-7515) (Fig. 10) having the most potent neurotrophic effects [175]. Upstream regulators of the JNK pathway were co-transfected into cells with JNK1 in the presence or absence of CEP-1347 and JNK1 activity measured by an in vitro kinase assay. This led to the identification of MLKs as a target for CEP-1347 [176]. CEP-1347 directly inhibits the kinase activities of the MLK family members in vitro with nanomolar $IC_{50}$ values [177] that are in the

**Figure 9** The c-Jun N-terminal kinase (JNK) pathway in cell death. See text for details.

**Figure 10** The Structures of K-252a, CEP-1347, and CEP-11004.

same range as $EC_{50}$ values for survival promotion in intact neurons [178, 179]. The related indolocarbazole analog 3,9-bis-[(isopropylthio)methyl]-(8*R**,9*S**,11*S**)-(−)-9-hydroxy-9-methoxycarbonyl-8-methyl-2,3,9,10-tetrahydro-8,11-epoxy-1*H*,8*H*,11*H*,-2,7*b*,11*a*-triazadibenzo(*a,g*)cycloocta(*cde*)trinden-1-one] (CEP-11004) (Fig. 10) also inhibits MLK1, MLK2, and MLK3 with nanomolar affinity [177].

CEP-1347 and CEP11004 have broad neuroprotective effects in vitro, inhibiting NGF withdrawal-induced cell death [177, 178], trophic factor-deprived spinal cord motoneuron death [179], $MPP^+$-induced neurotoxicity [177, 180], and β-amyloid-induced cortical neuron death [177, 181]. Inhibition of JNK pathway signaling by CEP-1347 also preserves metabolism and growth of neurotrophic factor-deprived neurons, thereby maintaining not only survival but the "quality of life" of neurons [182]. More recent findings suggest that in addition to the direct inhibition of the JNK pathway, the indirect activation of the phosphatidylinositol 3-kinase/Akt pathway via Trk activation is important for MLK inhibitor-mediated long-term neuronal survival and trophism [183, 184].

Neuroprotective effects of CEP-1347 in vivo include prevention of developmental programmed and axotomy-induced motoneuron cell death [185], basal forebrain cholinergic neuron death caused by fimbria-fornix transaction [186] or excitotoxins [187], and MPTP-induced substantia nigra dopaminergic cell loss in rodents [188] and nonhuman primates [189]. Additionally, systemic administration of CEP-11004 to mice is reported to inhibit the MPTP-mediated increase in phosphor-MKK4 in the substantia nigra and attenuated the MPTP-mediated loss of striatal dopaminergic terminals [177].

There is increasing evidence that neuroinflammation driven by abnormal or prolonged glial cell activation contributes to the pathogenesis and progression of Alzheimer's disease. Nornally, glia become transiently activated in the healthy brain in response to a number of stresses and generally act to return the CNS to homeostasis. However, the neuroinflammation hypothesis of Alzheimer's disease progression proposes that stresses such as amyloid peptide result in increased levels of inflammatory molecules produced by chronically activated glia, leading to neuron damage, inducing further glial activation, thereby resulting in a vicious cycle of neuroinflammation and neurodegeneration [190]. Indeed, activated microglia can cause neuronal cell death in vitro [191–193]. Interestingly, pharmacological blockade of MLK has been described to inhibit pro-inflammatory cytokine release from lipopolysaccharide- and amyloid β-peptide-stimulated microglia in vitro, and brain tumor necrosis factor-α (TNF-α) production induced by intracerebroventricular injection of lipopolysaccharide in mice [194, 195]. Modulation of the inflammatory response with MLK inhibitors conceivably may be of therapeutic benefit in retarding the progression of Alzheimer's disease pathology, as well as neuronal cell loss and neurodegeneration in other CNS disorders resulting from trauma, ischemia, or inflammation.

Amyotrophic lateral sclerosis is a fatal neurodegenerative disorder characterized by progressive death of cortical and spinal motor neurons. As mentioned earlier, when administered to animal models, by cellular or gene therapy, neurotrophic factors were effective in slowing motor neuron degeneration [196–199]. However, clinical trials failed to demonstrate efficacy, probably due to the poor absorption, distribution, and metabolic properties of these polypeptides [29–35, 200]. Interest has, therefore, turned toward identifying small molecules that can mimic trophic factors and support motor neuron survival and thereby treat motor neuron diseases. Using a phenotypic cell-based screening approach, a collection of approximately 40,000 low-molecular-weight compounds was assessed to identify small-molecule therapeutics. This led to the discovery of cholest-4-en-one, oxime (TRO19622) (Fig. 11), as a potential drug candidate [201]. In vitro, TRO19622 promoted motor neuron survival in the absence of trophic support, and in vivo the compound rescued motor neurons from axotomy-induced cell death in neonatal rats and promoted nerve regeneration following sciatic nerve crush in mice [201]. In $SOD^{G93A}$ transgenic mice, a model of familial amytrophic lateral sclerosis, TRO19622 treatment improved motor performance, delayed the onset of the clinical disease, and extended survival. TRO19622 bound directly to two components of the mitochondrial permeability transition pore: the voltage-dependent ion channel and the translocator protein 18 kDa (or peripheral benzodiazepine receptor), defining these as potential new therapeutic targets for the diverse traumatic and genetic lesions of the motor system that involve mitochondrial dysfunction [201].

**Figure 11** The Structure of TRO19622. TRO19622 exists as a stable mixture of syn- and anti-isomers of cholest-4-en-3-one, oxime.

## 10 CONCLUDING REMARKS

It has long been hoped that the power of neurotrophic factors to regulate neuronal cell survival in the developing nervous system could be harnessed for the treatment of neurodegenerative disease. Preclinical data suggest that subcutaneous or intravenous administration of neurotrophic factors may be effective for the treatment of peripheral and central nervous system diseases. In spite of such encouraging experimental findings, clinical studies have proven largely disappointing [202]. Not only have neurotrophic proteins failed to show a beneficial effect, but in some cases adverse side effects were noteworthy. Therapeutic benefit may be dependent on the extent of neurodegeneration before therapy initiation, and, although studies will be difficult, assessment of the effects of neurotrophic factors on the rate of progression over sufficiently long time frames may well be critical in determining their ultimate efficacy.

A detailed understanding of neurotrophic factor-receptor interactions and intracellular signaling [203] has been crucial in the design of peptidyl and nonpeptidyl small-molecule neurotrophin mimetics that interact directly with the receptor, or which potentiate neurotrophin activation of its cognate receptor [204, 205]. Another example of how such knowledge has been exploited is that of the $p75^{NTR}$, which can promote cell survival in the absence of Trk receptors. A pharmacophore designed to capture selected structural and physicochemical features of a neurotrophin domain known to interact with $p75^{NTR}$ was applied to in silico screening of small-molecule libraries to select neurotrophic compounds. In spite of such successes, several chemical entities directed against key targets involved in the apoptotic process (mixed linkage kinases [MLKs]; glyceraldehyde 3-phosphate dehydrogenase [GAPDH]) have proved ineffective in Parkinson's disease patients, although robust neuroprotective activity was demonstrated in multiple in vitro and in vivo models of neuronal cell death [206]. Reasons for failure are potentially many, including possible redundancy in death pathways, neurons being "resuced" but not functional, pharmacokinetic behaviors between patients, and the relevance of current animal models to the disease in humans.

In spite of these challenges, the development of neurotrophic compounds is potentially very rewarding and appears to offer real promise for disease modification. Neurotrophic drug development, however, has historically been a high-risk approach. Nonetheless, novel emerging targets and technological improvements, as well as the development of biomarkers that can act as surrogates to assess drug activity at the defined molecular target together with a more focused effort on translational medicine approaches [207], may facilitate the development of neurotrophic small molecules with lower associated attrition rates.

## 1 INTRODUCTION

Cancer is a devastating disease that is often fatal. Even with therapy, many patients will die. According to the World Health Organization (WHO), cancer was responsible for 7.8 million (13%) of 58 million deaths worldwide [1]. Due to this, it is no surprise that anticancer drug research is one of the most funded and vigorously pursued fields of research in the world today. Cancer remains a leading cause of morbidity and mortality throughout the world. In the United States, the pharmaceutical industry has exploded with the production of many new therapeutic agents. Anticancer drugs make up a great deal of these agents.

The quest for anticancer agents is fraught with difficulty. Anticancer drugs have typically been limited due to the severity and frequency of adverse effects seen in patients. *Chemotherapy*, as anticancer drugs are commonly termed, is often feared by patients. As research has progressed, we have been able to find more agents that are active against a variety of cancers. With improvement in our understanding of cancer, these agents have been designed to be less toxic to patients. Despite this, toxicity remains a major concern with anticancer agents.

The toxicity of anticancer agents can be attributed to the subtle differences in cancerous cells when compared to normal healthy cells. A cancerous or malignant cell is essentially a cell that has gone out of control. These cells grow, divide, and spread relentlessly. Their life spans are often infinite. In addition to this, they have the ability to invade other tissues and cause organ damage. Cancerous cells do not typically provide any beneficial biologic function and will replace normal healthy tissue. They aggregate as abnormal tissue, often called tumors. The spread of these tumors result in severe morbidity and mortality. The mechanisms behind the malignant cells erroneous processes often protect them from normal host defenses and chemotherapy. Anticancer agents are imperfect and cannot recognize all the subtle differences seen in malignant cells. They often can only target rapidly dividing cells. The result is damage to normal, healthy cells that reproduce more often. These are often the cells of the gastrointestinal tract, the bone marrow, and the sex organs. Additionally, some of these agents can have drastic effects on other normal healthy tissues, including the cardiovascular and neurological systems. Damaging these organ systems with drugs can cause further medical problems in already ill patients.

In addition to their ability to "hide" from the host's immune system, malignant cells have the ability to rapidly adapt to toxic conditions. For instance, a chemotherapy agent that might show activity in malignant cells at one point in time may eventually lose its ability to damage that cell type in the future. This is due to the resistance mechanisms present in malignant cells. These resistance mechanisms can be either innate or acquired. Alterations in drug transport mechanisms, drug targets, drug metabolism, DNA (deoxyribonucleic acid) repair, DNA synthesis, and apoptosis mechanisms can all contribute to resistance. A recurring problem in anticancer research is to find more agents to treat these resistant cells.

Thankfully, the rise of technology, specifically mathematical and chemical modeling, has been of great benefit to anticancer drug research. The progression of new technologies such as high-throughput screening, bioinformatics, genomics, and proteomics have created a surge in the understanding of cancer biology and therapy. These technologies are already being credited for helping to create a number of new promising anticancer agents. We are only at the forefront of understanding their utility in anticancer research. It can be presumed that these technologies will continue to help us produce amazing breakthroughs in anticancer drug discovery.

In addition to the newer technologies, we must not forget the standard approaches for drug discovery. This is where we find our roots in anticancer drug discovery. Areas such as natural products research have led to the development of further research avenues, such as combinatorial chemistry. Many of the drugs created from these older research methods are still quite useful today. A majority of them remain first-line agents for the treatment of a variety of cancers. These areas of research are still actively producing new compounds.

The process of anticancer drug development is quite lengthy. It can take well over 10 years for an anticancer drug to go from preclinical development to its final use in a clinical setting [2]. It is therefore important to have a basic understanding of the preclinical and clinical testing that is performed to develop an anticancer agent. There are over 100 agents approved for the treatment of various cancers worldwide [3]. Hundreds more are in the stages of clinical and preclinical testing and may never make it to a clinical setting.

This chapter is meant to give a basic understanding of the methods of anticancer drug research. This will be achieved by giving a background of where anticancer drug discovery has come from to where it is going. From natural products research to DNA microarrays, all facets of anticancer drug research will be explored. Additionally, the current classes of anticancer agents will be explained. Significant detail will be given to the newer agents that are being developed. Future directions will also be highlighted throughout the chapter. In the end, this chapter is designed to stimulate thought among researchers interested in anticancer drug discovery. With more insight into the treatment of such a devastating disease, we can hope to improve the quality of life for millions.

## 2 NATURAL PRODUCTS

### 2.1 Introduction

The development of drugs from sources in nature is the oldest method of drug discovery. Drugs such as digoxin, penicillin, and even aspirin trace their roots to natural sources. It is no surprise that many chemotherapeutic drugs have been derived from naturally existing sources. It is estimated that at least two-thirds of the anticancer agents currently in use are either directly isolated from natural sources or are a semisythetic version of natural compounds [4]. The main question pertaining to these compounds is aimed at why anticancer compounds exist in nature. Perhaps the simplest explanation to this is evolution.

Over the course of evolution many organisms develop adaptations that give them advantages over their competitors over different stresses in the ecosystem. These adaptations are usually the development of chemical and biochemical compounds. On a cellular and molecular level these compounds can often include mechanisms that cause cell cycle arrest, programmed cell death, and even direct toxicity. These intracellular systems may allow an organism to have a survival advantage against predators or make them a more effective predator.

By understanding these basic principles, we have seen the benefit in the field of oncology. The ability to isolate active compounds has improved as our skills in organic chemistry and biochemistry have evolved. Our understanding of the cell cycle further enhances our ability to understand the utility of natural products. Despite the promising findings in natural product chemotherapeutics, there is a great deal of difficulty and complexity to this field.

### 2.2 Methods of Discovery

The easiest way to think of the natural product drug discovery process is to view the process from start to finish. The first step in natural product research is taken by finding an organism of interest. This organism is then harvested in fairly large amounts. Once an adequate amount of material is harvested, a crude large-scale extraction is performed on the organism. This extraction is performed by using various different organic solvents to extract hundreds to thousands of compounds from the organism. These crude extractions are then tested for activity on cancer cell lines. If promising activity is noted with one particular extract, further studies will be done on this. Using modern organic chemistry techniques such as high-performance liquid chromatography (HPLC), nuclear magnetic resonance (NMR), mass spectroscopy, and infrared spectroscopy the exact chemical composition of the active compound or compounds from a given extract can be ascertained. Once the structure and chemical composition of a possible drug is known, steps toward synthetic or semisynthetic development of a drug can be pursued.

One factor that helps determine which organism to use is in regards to supply. Due to the large amount of biologic material that is needed for experimentation and eventually clinical use, one must be selective in choosing an organism that is easily accessible and is in adequate supply. An excellent example of this is the anticancer agent paclitaxel (Taxol). Paclitaxel was initially found from the bark of the Pacific yew tree. The drug was initially found in 1967 [5]. From its discovery in 1967 until 1993 almost all paclitaxel used in research and treatment was derived from the bark of the Pacific yew tree (*Taxus brevifolia*). To create a single dose of paclitaxel, a proportionally large amount of bark was needed due to very poor yield. Due to the large amount of bark needed, there was a great deal of concern about the number of yew trees being harvested [6]. The tree, of course, took many years to reach a point at which it could be utilized to harvest the drug. Even with planting new trees, the demand was starting to outweigh the supply. It was feared that the yew tree would eventually become extinct. Due to this concern, a great deal of work was done to try and develop a way to synthetically or semisynthetically make paclitaxel. Initial efforts were thwarted by inefficiency and impractical methods; however, in 1992 a feasible method was found. A group led by Robert Holten eventually found that by using the needles of the *Taxus baccata*, a yew tree related to *T. breviolia*, one could semisynthetically make paclitaxel with an 80% yield [7].

Ethics also plays a role in the field of natural product drug discovery. The more intelligent a life-form is, the less likely it is that its use will be accepted. For instance, the majority of drugs are found from plant, simple marine, and microbial sources. Concerns may arise when a more complex life-form is investigated for drug discovery. Destroying intelligent life for the pursuit of drug development creates an ethical dilemma. At what point do we determine an organism should not be utilized? This is a question that researchers should be pondering when pursuing a possible new source for a natural product. Other ethical dilemmas lie in areas such as habitat destruction and annihilation of certain species.

The number of organisms on this planet is vast, therefore making it difficult to understand which organisms will produce active compounds. Due to the vast array of organisms on this planet, searching for anticancer drugs can sometimes seem like "looking for a needle in a haystack." In order to decide what organisms to pursue for studies, the general approach has been to look at organisms that have historically had activity. For this reason, the majority of anticancer agents have been found from marine, plant, and microbial sources.

### 2.3 Marine Sources

Ocean's cover about 70% of the Earth's surface, which makes it obvious that a large majority of life on this planet can be found under the sea. The biodiversity of these life-forms creates great potential for finding anticancer agents. As we have become more adept at deep-sea diving and ocean exploration, finding these organisms has become much easier. Additionally, advances in aquaculture technology has helped us to cultivate the amount of biomass needed for research.

The first marine anticancer agents discovered were spongouridine and spongothymidine. These were derived from the sea sponge *Cryptothethya crypta* [8, 9]. From these agents the commonly used drug, cytosine arabinoside, was synthesized. Further expanding on sea sponges and other related sea life, many exciting drugs have been found. The bryostatins are one class of drug that were isolated from the marine bryozoan *Bugula neritina*. This group of drug is noted as having protein kinase C activity [10]. They have shown promise as single agents but are most notably showing a great deal of activity as synergistic agents. At this point, bryostatins are in phase II clinical trials [11, 12].

Other agents derived from sea life include the ecteinascidins isolated from the Caribbean sea squirt, dolastatin [13] from the Indian Ocean sea hare *Dolabella auricularia,* didemnin B [14] from the tunicate *Trididemnum solidum*, aplidine [15] from the Mediterranean tunicate *Aplidium albicans,* and kahalalide F [16]from the Hawaiian mollusk *Elysia rufescens*. All of these agents have shown activity in preclinical studies and are now in various stages of clinical trials. Hundreds of other agents are now being studied in preclinical trials [17–20].

### 2.4 Plant Sources

As previously mentioned, paclitaxel is a famous example of an anticancer drug developed from a plant source. Interestingly enough, various plants have been known to play roles in cultural and tribal remedies. Many of these plants that have been used in traditional remedies have actually been shown to have pharmacologically active agents when they are purified. An example of this is the Madagascar periwinkle *Cathranthus roseus*. This plant was used as a traditional remedy for diabetes in several cultures. When the plant was researched to find out if there were any agents that could be utilized for diabetes, an interesting discovery was made. The vinca alkaloids, vinblastine and vincristine, were found instead. These drugs play a vital role in the field of oncology to this day [21].

Some drugs from plant and other sources have only weak activity or may have severe side effects that

limit their use clinically. This is why semisynthetic derivatives are sometimes pursued. The camptothecins are an excellent example of this. The Chinese ornamental tree *Camptotheca acuminate* produced the camptothecins [22]. They were noted to have good activity in cancer cell lines; unfortunately, they had a great deal of systemic toxicity. Semisynthetic derivatives were created and the two agents topotecan and irinotecan were born. These two agents are strong inhibitors of DNA topoisomerase I. They have been shown to have exceptional activity in a wide variety of tumor types. Due to this, further work is currently being done to find more semisynthetic derivatives of this class.

Multiple other plant-derived products are currently being investigated. Homoharringtonine is a plant alkaloid that is isolated from the Chinese tree *Cephalotaxus harringtonia*. This agent has good activity in a variety of hematologic malignancies and is in preclinical studies [23]. Elliptinium is a DNA topoisomerase II inhibitor and DNA intercalater found from the Fijian medicinal plant *Bleekeria vitensis*. This agent has been shown to have preclinical activity in metastatic breast cancer. Unfortunately, systemic toxicities are limiting its use in clinical trials [24]. The combretastatins are a group of drugs isolated from the African bush willow *Combretum caffrum*. They are thought to work by inhibiting tubulin polymerization, which causes rapid vascular shutdown vial endothelial cell apoptosis. The combretastatins are currently in clinical trials [25].

### 2.5 Microbial Sources

Microbial organisms have provided us with a great deal of drugs. Perhaps penicillin is the most well-known example throughout medicine. Oncology too has benefited from microbial sources of drugs. Many chemotherapeutics including the anthracyclines (doxorubicine, daunorubicin, epirubicin, and idarubicin), bleomycin, actinomycin, and mitomycin are from microbial sources. Microbial organisms are an excellent source for many reasons. One of the major reasons is that they reproduce rather rapidly. This allows for a great deal of drug to be available for research and clinical use. The need for synthetic drugs from these sources is much less than with slower growing organisms in the plant and animal kingdoms.

Epothilone A and B are two drugs from the myxobacterium *Sorangium cellulosssum*, which were initially investigated as antifungals but now are shown to have activity in human cancer cell lines. This class of drug works in a similar manner to paclitaxel and is in preclinical and clinical studies at this time [26].

### 2.6 Conclusion

Natural products have been present in anticancer drug research since the beginning. As we enter the era of rationally designed drugs, there is a question as to what role natural products will play. It is obvious that there could still be thousands of drugs out there in nature. As long as researchers continue to pursue this area of drug discovery, there will be new drugs developed from natural sources. Perhaps the most exciting concept to evolve in natural product drug discovery is the seemingly unending ability of chemists and biochemists to create semisythetic and synthetic versions of these drugs, which will eventually eliminate the need to destroy a large amount of biologic material to treat cancer.

## 3 COMBINATORIAL CHEMISTRY

Combinatorial chemistry is often referred to as one of the greatest advances in medicinal chemistry. Since its development, combinatorial chemistry has shown promise in the field of oncology. It has drastically altered the method in which anticancer compounds are synthesized. Combinatorial chemistry essentially involves the rapid synthesis or computer simulation of a large number of different but structurally related molecules.

The traditional approach in medicinal chemistry involved creating structurally related compounds individually, and then eventually sets of analogs would build up serially. When the analogs were developed in this way, they would require individualized reaction sequences and purification methods. This was very labor intensive and costly. Combinatorial chemistry on the other hand, works by using a defined pathway of bond-forming reactions to combine sets of simple molecules or building blocks to give complex products in a small number of steps. This can be easily repeated over and over again, thus allowing for libraries or large numbers of analogs that can be created in an organized and efficient manner. This repetitiveness allows for automation, which in turn allows for a format that is amenable to high-throughput screening.

Combinatorial chemistry was initially developed in the 1960s by R. B. Merrifield. He initiated the concept when he was studying the synthesis of peptides. Merrifield developed a concept called solid-phase synthesis (SPS) [27]. SPS is essentially a method in which molecules are bound on a bead and synthesized step-by-step in a reactant solution. As technology advanced and computers became more readily available, this process has become "digitalized."

The pharmaceutical industry has utilized combinatorial chemistry to develop hundreds of thousands of potential compounds per year. When an active compound is found, combinatorial chemistry can be used to optimize the compound, thus developing many different, but related compounds. These digital compounds are placed in a *virtual library*, which can contain thousands to millions of different compounds. Using other technologies such as quantitative structure-activity relationship (QSAR), these compounds are screened and the most promising subsets will be synthesized. Currently, there are five types of combinatorial chemistry libraries, which include biological libraries, spatially addressable parallel solid-phase or solution-phase libraries, synthetic library methods requiring deconvolution, the "one-bead one-compound" library method, and synthetic library methods using affinity chromatography selection [28].

### 3.1 Combinatorial Chemistry in Anticancer Drug Discovery

Combinatorial chemistry is currently being used in the discovery of many different anticancer drug classes. They have been shown to have utility in expanding upon drugs derived from natural products [29]. More recently, combinatorial chemistry has shown its effectiveness in investigating small-molecule protein kinase inhibitors. This includes the cyclin-dependent kinase inhibitors, the protein kinase C inhibitors, matrix metalloproteinase inhibitors, protein phophatase inhibitors, and tyrosine kinase inhibitors.

The cyclin-dependent kinase (CDK) family of enzymes are integral in controlling the cell cycle progression. They work primarily at the cell cycle checkpoints. In cancerous cells they result in aberrant cell cycle control. This may stem from a tumor suppressor gene malfunction or from the activation of oncogenes. Tumors with abnormal CDKs will have increased CDK activity. The majority of CDK inhibitors currently used inhibit the adenosine triphosphate (ATP)-binding domain of the CDKs. The active component of small-molecule CDK inhibitors usually involves the purine pharmacopore. Combinatorial chemistry is currently being used to create libaries of compounds with variations on the purine pharmacopore [30].

Protein kinase C (PKC) is another kinase involved in the regulation of cell growth and signaling. It involves a family of at least 12 closely related serine–threonine kinase isoforms. They have been a quite interesting target for targeted anticancer agents. The development of clinically useful PKC inhibitors has proven to be more difficult than expected due to the complex nature of the PKC signal transduction pathways and the lack of isoform-specific modulators of PKC activity. One example of this is diacylglycerol (DAG). DAG is a second messenger that activates and recruits some PKC family members to the plasma membrane. DAG has been exploited using combinatorial chemistry to create a library of 16 members that are all derived from the active DAG enantiomer [31].

Inhibitors of DNA-dependent protein kinases (DNA-PK) are yet another group of kinases that play a role in cell development. They are serine–threonine protein kinases that work by detecting and repairing DNA double-strand breaks. By inhibiting these kinases, one could allow for radiosensitization and chemosensitization. Combinatorial chemistry is currently being used on one class of these inhibitors, the thiopyranones. Work with this class using combinatorial chemistry has been able to produce an analog that is one of the most potent DNA-PK inhibitors to date [32].

Tyrosine kinases are extremely popular targets for inhibition in anticancer therapy. A large number of small molecules are currently in development in this class. The major target of inhibition is the ATP-binding site of the tyrosine kinase. Combinatorial chemistry is credited as helping develop the multikinase inhibitor, sorafenib [33]. Further work is being done using combinatorial chemistry to find analogs of various known active tyrosine kinase inhibitors.

With the rise of computerized technologies, combinatorial chemistry has been born. It is now a firmly established component of drug discovery, including the field of anticancer drug discovery. Combinatorial chemistry allows us to expand further on what is known. This, in turn, affords the opportunity to expand one drug into many, some of which could be more effective than the initial compound. There is no doubt that combinatorial chemistry will continue to play a vital role in anticancer drug discovery.

## 4 HIGH-THROUGHPUT SCREENING

As anticancer drug discovery has progressed, the number of new drugs available to the research pipeline is enormous. Due to the volume of new drugs, there has been a push to increase the efficiency of the drug development process so that only drugs with the best efficacy with fewer side effects are ultimately approved for use in patients. High-throughput screening (HTS) is one technology that has aided in this quest.

### 4.1 High-Throughput Screening

High-throughput screening refers to the automated method for rapidly evaluating thousands of chemical

compounds. This method has evolved a great deal as technology has progressed. HTS essentially started out as a more efficient and rapid method of doing regular laboratory assays in bulk. The assays available at that time were limited in their throughput and output. This meant that it could take months to complete the assays. Eventually, major changes in assay design, data capture, data analysis, and quality control were discovered. As this occurred, HTS also advanced by integrating these technologies with robotics to allow for improved automation. As a result, HTS became more systematic and industrialized. The current HTS systems involve similar concepts including robotics, incubators, liquid dispensing mechanisms, sensors, data collection software, and data analysis software [34].

The basic principle of HTS is to start with a library of compounds and systematically test a large number of these on specific assays to determine if they have a desirable effect. Once a compound is noted as having the desired effect (a *hit*), it will move on through a battery of more testing. If a hit passes these tests, it will be a *lead compound*, which will go on for more detailed experiments.

The easiest way to understand the current methods of HTS is to think about each crucial component of the process. These components include the compounds being tested, the drug targets, assay design, reagent design, the screening method, quality control methods, data analysis, and the process from which hit compounds are progressed to lead compounds.

### 4.2 Compounds

As previously mentioned in other sections, there is a vast supply of potential anticancer agents available in various stages of development. HTS is currently being used to evaluate compounds derived from natural products, medicinal chemistry, and combinatorial chemistry.

Natural products have long been researched as potential anticancer agents. There are already a large number of anticancer agents that have been derived from natural products that are currently being used clinically. Since more technologically sophisticated methods of developing drugs have evolved, the use of HTS in this field has been dwindling. HTS is still currently being used in this field to some extent. The best example of this is the process of prefractionation of extracts [35]. As mentioned previously, extracts from natural products are obtained to be tested on cancer cell lines.

These extracts have been quite crude and contain hundreds to thousands of potentially active compounds. Prefractionation is an HTS method being used to reduce the time taken after initial screening to help identify the active components in a crude extract. Several procedures have already been established and range from solvent/solvent extraction to chromatographic procedures (adsorption chromatography, high-performance liquid chromatography [HPLC], medium pressure liquid chromatography [MPLC]). These typically have had a low level of automation. One of the first commercially available automated methods for the extraction and separation of plant material is the HPLC-based workstation, Sepbox. This automated method incorporated efficient fractionation of crude extracts to work toward obtaining pure compounds. Another newer method of prefractionation that has been developed works by using solid-phase extraction (SPE). This works by mixing the organic extract with an initial solvent and running it through solid-phase extraction using adsorptive resins. The product of this is then fractionated into several samples, and they are subsequently mixed with an organic solvent and ran through another SPE step. The samples are again fractionated and the process can be repeated as often as desired. Ultimately, the final compound is a more pure concentration of the desired fraction of the initial crude extract.

Combinatorial chemistry is a relatively new concept that has used technology to create vast libraries of potential anticancer agents. The vast number of these drugs are often called *libraries*. These libraries are essentially compound collections developed by researchers that may be potentially tested to assess their anticancer properties. Combinatorial chemistry has exponentially increased the number of potential anticancer agents in preclinical research. This has proven to be both a boon and a bane, however.

The vast number of compounds make it difficult to decide which agents should be tested first and what agents may be the most promising. We have been very limited in testing these compounds in the past due to our somewhat slow standard preclinical testing techniques. Perhaps this is why HTS has proven to be so helpful. HTS allows for rapid testing of thousands of compounds at once. The most common approach, sometimes called *full-deck screening*, has been to test an entire library of compounds at once using automated methods. This method is good as all potential agents are tested, however, it is both costly and more time consuming. An alternative to this has been to use *diversity decks*, which are more focused libraries that reorganize the full deck to format the compounds into chemically related groups [36]. These groups are then tested separately from the entire library. The more active groups are then tested further, rather than doing further testing using the entire library. These methods differ and have varying advantages and disadvantages. Several factors have to be considered when utilizing these methods of HTS and include cost, time, and the variability of the

compound library. Regardless of this, it is obvious that HTS has proven to be very helpful in deriving compounds through combinatorial chemistry.

The final group of compounds that utilize HTS are compounds present in medicinal chemistry collections [37]. These collections are essentially libraries of compounds that have been collected over the years from pharmaceutical research. When a promising anticancer agent is discovered, there are often a number of other, similar compounds that are discovered along the way. Because time and money do not allow for testing of all of these compounds, they are often stored in medicinal chemistry libraries. By using HTS methods similar to those used in combinatorial chemistry, new lead compounds are being developed from these libraries.

### 4.3 Target Sources

As our understanding of molecular biology and biochemistry has evolved, a number of cellular targets have been identified as targets for anticancer agents [38]. Using this knowledge, we can apply HTS techniques to help screen agents that will focus on these targets. These targets include tyrosine kinases, matrix metalloproteinases, DNA repair enzymes, proteases, G-coupled proteins, and many others. By using HTS methods, one can essentially evaluate libraries of compounds in regards to their activity on one of these specific targets. Using automation, one can screen in a relatively rapid manner. This method of study is quite different from traditional techniques in which a potential compound was evaluated to see if it had activity in cancer cell lines and the mechanism of action was determined later. Using target sources, one can find drugs that have the desired mechanism of action first, then these agents can be tested on cell lines for overall activity later on.

### 4.4 Assay Design

HTS incorporates the use of specific assays. These assays essentially are the backbone of the experiments. The assays are the environment and conditions in which the reagents will be tested. In HTS, these assays must be small, efficient, and easily reproducible. The easiest way to think of these assays is in regards of their two major components, screen construction and screen validation [39]. Screen construction creates the basis of the experiment. It sets up the optimal conditions and the constraints of the experiment being done in the assay. These components all pertain to the ultimate goal of the assay. Kinetic parameters are also set during screen construction. More importantly in HTS, screen construction must incorporate the concept of automation to help create a more streamlined and efficient backbone for experimentation.

### 4.5 Screen Validation

HTS essentially involves the "amplification" of lower throughput methods. In essence this means if one was to use a small number of plates to run experiments using low-throughput methods, in high-throughput methods, this number is amplified to thousands of plates. With this amplification, the margin of error can also increase a great deal. When designing HTS systems, screen validation is therefore an integral component. Screen validation ensures that the assay or assays will work within the constraints of the experiment. It also ensures that the experiment will be easily reproducible and predictable. This step is often done prior to initial experimentation and will also be ongoing throughout the experiment. If a large amount of variability or "noise" is noted in the experimentation, the assay may need to be redesigned.

### 4.6 Reagent Design

The reagents are the integral ingredients of the experiment. In HTS it is important to consider the types of reagents being used when designing the HTS system. Solubility, compatibility with the assays, wear on the machinery, use of radiolabeled compounds, and storage are all important factors to consider when using an HTS system. For instance, if a specific compound is relatively unstable and requires special storage, this may prove to be difficult with some HTS systems and may increase the cost of experimentation. Another factor to consider is the ease of creating large amounts of the reagent. If it takes a great deal of time to create the reagents, it may not be worthwhile to use an HTS system, as the reagents themselves may be the rate-limiting step. Likewise, one must consider the amount of reagent needed for the HTS system. If it is not feasible to have the amount needed for a specific HTS system, it may be useful to scale down assays to accommodate the reagents. Although HTS has made screening methods much easier with automation, it can be difficult if the wrong types of reagents are used.

### 4.7 Quality Control

As mentioned before, HTS systems can increase the amount of variability and error in experimentation. This is sometimes referred to as noise. Many different factors contribute to this noise. These factors include compound variability, kinetics, stability of the compound and the assay, and assay variability. When designing HTS systems, assay design, screen validation, and reagent design are helpful in minimizing this noise; however, there is always a need for quality control. Quality control is often done throughout the experimentation process. It provides a

method to quantify and record the variations in the experiment. This can be done through a variety of methods and is not always entirely computerized. For example, an experimenter may analyze the results of daily experimentation, and, if there is a degree of variability that is greater than desired, the experimentation may be halted and steps to decrease the variability may be taken.

### 4.8 Data Analysis

As HTS is becoming more efficient and productive, the volume of data produced is becoming astronomical. It is, therefore, very important to have a similarly efficient and capable data analysis system. As computer hardware and software have improved, this step has become much easier [40]. The hardware must be capable of performing processes at high speeds and must have adequate memory to store the data. The software must be able to perform all the data analysis operations, including recording, basic calculations, statistics calculations, data visualization, and error. When these calculations are complete, one can surmise the activity of the various compounds being tested and compare their activity to other compounds. The ultimate goal of data analysis in HTS is to be streamlined and efficient, while at the same time allowing the researchers to determine which of the screened compounds should move on for further testing. An error in data analysis can easily make the rest of the HTS system invalid.

### 4.9 Hits to Leads

As the HTS system comes to an end, the desired result is the production of hit compounds. These compounds have essentially fit the desired parameters in the screen and will need to be tested further. After further testing, they will be termed lead compounds [41]. In order to become a lead compound multiple batteries of tests will be performed. These can be automated in a manner similar to the prior HTS system or they can be more manual. The tests can also be hypothetical and will not require further bench research at all. Nonetheless, several different factors must be evaluated for a hit compound to become a lead compound. These factors include things such as cost of production, availability of the drug, solubility, the delivery vehicle, patentability, and other special considerations. The ultimate goal of this further testing is to find the most promising overall compounds in a given library of compounds.

HTS is a very complex and extensive process. The design of the system is perhaps the most important aspect of HTS. As technology continues to progress, HTS systems will evolve into systems that are more efficient, more complex, and will have decreased variability. They are an integral component of anticancer drug discovery and will continue to be important as potential drug libraries continue to expand.

## 5 BIOINFORMATICS

Computer technology is playing a vital role in anticancer drug development. Perhaps the use of computers is the most obvious in the fields of bioinformatics and computational biology. Bioinformatics is a field that melds biological sciences (genetics, cellular biology, systems biology, chemistry, and biochemistry) with computer sciences (applied mathematics, statistics, artificial intelligence, modeling, and informatics). This field essentially started as a basic adjunct to standard chemical and biochemical experiments. It rapidly evolved when it was utilized in the areas of combinatorial chemistry and high-throughput screening. By applying the expansive computer technologies of today, the utility of bioinformatics has become substantial. The basic premise of bioinformatics is to use computer technology to solve chemical and biochemical problems. Examples of this include using computers in analyzing and predicting RNA (ribonucleic acid) and DNA sequences [42], analyzing and predicting gene expression, identifying possible new drug targets, and analyzing protein structure and intracellular location [43]. Its utility in solving these types of problems has led to bioinformatics to be used in the drug discovery field.

Bioinformatics essentially allows for virtual experimentation, sometimes called in silico experimentation. This type of experimentation is beneficial over standard "bench" research as it does not require the materials and time necessary in bench research. By applying known scientific principles together in a virtual environment, one can predict possible outcomes. The first step in using bioinformatics in anticancer drug discovery is to utilize computers to sort through the enormous amount of cancer research data. This concept is termed *data mining* [44]. The data of interest includes information about malignant and normal cellular genetics, protein makeup, signaling pathways, response to chemotherapeutic agents, and other biochemical characteristics.

Bioinformatics can be divided into two different categories, floating-point problems and integer problems [45]. Floating-point problems usually involve using complex algorithms that utilize chemistry and advanced physics techniques. Kinetics, protein structure and formation, metabolism, and molecular dynamics are common problems solved utilizing floating-point techniques. They can be focused on optimizing high-

throughput screening as they replace the actual "physical" chemistry steps that are needed to develop lead compounds. These methods are constantly evolving. The current hope is that in the near future these techniques will be able to perfectly model the processes in malignant cells down to the molecular level. By modeling these processes, in silico experimentation can be performed and the activity of different compounds can be predicted. Anticancer drug discovery could essentially be virtualized.

Integer problems are quite different than floating-point problems. This technology is typically algorithm based. The algorithms compare matching phrases and terms or characters in sequences. This makes it an obvious choice for solving genome sequencing problems as well as a host of other molecular biology problems. These processes can typically be done over high speeds, which is quite desirable in the field of genomics. Integer problem solving using bioinformatic technology was very useful in aiding in the discovery of the human genome.

Data mining is another technique included in the repertoire of bioinformatics. This works by combining statistical analysis with pattern discovery techniques. Data mining uses these methods to investigate vast libraries of data. It allows for the detection of intricate and subtle similarities between items that were previously thought to be unrelated [46]. This can be quite useful, particularly in clinical research. Factors such as patient demographics, treatment response to different drugs, genetic abnormalities of their cancer, and other items from the clinical record can be evaluated and similarities or differences can be unveiled and exploited. This is proving to be most useful in evaluating patients with specific gene expression profiles and their response to different treatments. By finding similar gene expression profiles and similarities in response to treatments, further research can be done to see why this is so on a molecular level. The best example of the utility of data mining can be seen in patients with HER2/neu positive breast cancer [47]. Trastuzumab is an agent that is used in patients with HER2/neu overexpression. HER2/neu is an oncogene that is overexpressed in some patients with breast cancer. Trazstuzumab targets this abnormal oncogene and has provided to be a therapeutic asset in this subgroup of patients. Unfortunately, HER2/neu overexpression is not that straightforward. Different groups of patients may have a greater or lesser degree of overexpression. Overexpression of HER2/neu requires a number of intracellular molecular processes. By using data mining to understand these processes better at a genetic and molecular basis, patient response can be better predicted and dosing of the medication can be better approximated. Additionally, clinicians may be able to decide whether or not the patient will need an additional chemotherapeutic agent based on data mining information.

There is another useful bioinformatic concept that involves the systematic study of various interactions in a biologic system, called systems biology [48]. Systems biology can be utilized in molecular biology to read and record the mechanisms of gene expression and regulation in order to model phenotypic expression. This modeling can essentially be used to predict phenotypes of certain genes. By utilizing this technology, it is possible to model the expression of oncogenes in malignant cells. By modeling these genes and understanding their phenotypes, new drugs can be developed.

Ultimately it is important to remember that anticancer drug discovery is based on the principles of finding drugs that target malignant cells. These cells have subtle differences when compared to normal healthy cells. By exploiting these differences, better drugs can be developed. Bioinformatics is useful in this aspect as one can simulate these differences in a computerized environment through in silico experimentation. It should also be known that many of the genetic and molecular differences in various cancers can vary in each individual. This can mean that the same treatment in two patients with the same type of cancer can have two very different effects. The ultimate goal of bioinformatics is to incoporate the principles of in silico experimentation with data mining capabilities and standard experimentation to essentially tailor treatments to an individual, based on their genetic and molecular uniqueness.

## 6 GENOMICS AND PROTEOMICS

Our understanding of the molecular biology of cancer has progressed dramatically over the past decade. As we grow to understand more about the genetics of malignant cells, we are now learning how to apply this to create new chemotherapeutic agents that target these genetic differences. Being able to target specific genetic abnormalities in cancer cells allows us the ability to tailor therapies that minimize systemic toxicity. The fields of genomics and proteomics are what allow us to realize these therapies.

Genomics is essentially the study of the function and interactions of genes in an organism's genome [49]. For centuries, it has been understood that there are diseases that seem to run in families. This knowledge has progressed over the years and in the 1980s we began to understand that mutated genes were responsible for some disease processes. In the field of oncology, a number of such genetic mutations have been identified [50]. As we identify these abnormalities, it is human

nature to investigate methods to more easily identify these mutations and ultimately use this knowledge for treatment. Perhaps this is why genomics has provided researchers with a plethora of information for the development of new drugs.

Proteomics is similar to genomics and is essentially the study of proteins [51]. This is based on better understanding of protein structure, pathways, and function. In cells, genes code for specific proteins that will often be used in certain intra- and extracellular processes. Proteomics provides additional understanding on how cellular processes occur. When combined with genomics, proteomics can provide detailed information on how cells grow, divide, differentiate, and die.

As our genomic and proteomic knowledge has progressed, researchers have seen the enormous potential in the field of anticancer drug discovery [52, 53]. The goal of anticancer research has been to develop treatments that are toxic to malignant cells, while sparing normal cells. By understanding the genetic basis of cancer, we are able to pinpoint the problems in malignant cells. After pinpointing the abnormal genes and subsequent proteins that they code for, one can try to tailor therapies to target these unique proteins. This method allows for the selective eradication of malignant cells.

Better understanding of cancer genomics and proteomics can give researchers and clinicians more information on the somatic genetic mutations present in specific types of cancer. Additionally, the mutant proteins produced from these gene mutations can be identified and their aberrant processes understood. Understanding these changes allows for better understanding of molecular abnormalities in these cells. This information can provide data by explaining the changes in growth, invasiveness, metastatic potential, drug resistance, and drug responsiveness in different tumor types.

### 6.1 DNA Microarrays

DNA is often termed the "building block" of life. This is evident in the growth and development of cancerous cells. Cancerous cells often come into being due to some error in cellular DNA. Whether this is an error in DNA repair or a de novo mutation, the end result can be abnormal cell growth and proliferation. As scientists have begun to understand the human genome and the proteins created from normal genes, they have also begun to understand abnormal genes and proteins.

A number of different genes and proteins can cause a cell to become cancerous. For example, proto-oncogenes are normal genes that can end up becoming oncogenes. This can occur through a variety of methods but is often due to mutations or abnormal expression of proto-oncogenes. The proto-oncogene then codes for proteins that regulate cell growth, differentiation, proliferation, and apoptosis. When these proto-oncogenes and their corresponding oncogenes are abnormally expressed, cell growth becomes abnormal. This abnormal growth leads to malformed tissues that do not provide the desired biologic function. These cells can in turn have an innate "immortality" and do not usually die like regular cells. This ends up in the development of cancerous cells.

Understanding these abnormal processes is just one step in the quest for anticancer agents. The next step is to determine how to stop these processes. As protein kinase inhibitors are becoming more popular in the treatment of cancer, we are finally able to see the benefits of this approach. The major problem remains. How do we know which types of cancerous cells will respond to what targeted agents?

DNA microarrays or "gene chips" have arisen as a means to try to solve this problem. This technology has been developed as a product of HTS and bioinformatics combined with the concepts of genomics and proteomics. These microarrays are a relatively inexpensive and flexible way to evaluate the gene expression in different cell types. Shortly after microarrays were developed, their use in anticancer research was realized [54].

A DNA microarray essentially consists of a solid surface with multiple nucleic acid polymers embedded on the surface. These nucleic acid polymers are essentially single-stranded gene fragments, which may include known or predicted variants and possible genetic polymorphisms [55]. The solid surface serves as a backbone and is usually made of silicone or glass, similar to microchips. This solid surface holds the nucleic acid polymers with a chemical matrix.

There are a number of different types of microarrays available. It is too lengthy to explain all of them in detail, but the same basic idea reigns supreme in each of these microarrays. These systems essentially work to utilize their nucleic acid polymers as probes to bind labeled free targets derived from a biologic sample. In cancer research, this sample is typically the complementary DNA (cDNA) of a malignant cell. The cDNA is essentially the synthesized DNA from the cell's messenger RNA via the action of the reverse transcriptase enzyme. The resulting cDNA is labeled so that it can be followed throughout the microarray process. This cDNA selectively binds to its corresponding nucleic acid polymer. The resulting product then gives off a signal, which is usually fluorescent in nature. This allows the product to be read by the microarray's sensing mechanism. This is then analyzed and recorded by the microarray's corresponding software. Further statistical analysis

can then be done and the final readout of the genetic expression of these cells can be realized.

The microarrays are designed to be simple to use. They can facilitate gene expression measurements for thousands of different genes at the same time. They are easily reproducible and can measure a number of genes expressed in parallel. Their corresponding software can be used to make a multitude of complex calculations and solve multiple statistical questions. The result of a DNA microanalysis is data regarding the genetic expression of specific cell types. When this is applied to malignant cells, the resulting data gives insight on the genetic expression of that type of malignant cells.

Years ago, it may have been useless to understand the genetic expression of malignant cells. However, with our knowledge of the normal human genome, these differences can be exploited. For instance, if a specific type of cancer cell overexpresses a certain genetic polymorphism, the resulting protein that is coded for can be further evaluated. This abnormal protein may not cause any specific problems, but it may show significant differences from normal, healthy cells. On the other hand, the abnormal products of this overexpressed gene can lead to the major driving force for the cancerous cell's ability to grow, divide, invade, and live on relentlessly. By looking at the abnormal products of the overexpressed genes, one can find potential targets for anticancer therapies.

In addition to finding new targets for anticancer therapies, DNA microarrays can help researchers to better understand drug resistance [56]. Drug resistance is quite complex and can be present innately or acquired. Either way, drug resistance poses a huge problem in the treatment of cancer. A tumor that may be sensitive to a specific agent may eventually become resistant to that agent and many other agents. DNA microarrays are used to evaluate for genetic mechanisms in this resistance. By understanding the genetic mechanisms in resistance patterns, different treatment plans can be developed. Some hope to evaluate these resistance patterns by using DNA microarrays to compare the genetic expressions in a set of chemosensitive cells versus chemoresistant cells. By analyzing the genetic differences in these cells, one can understand the proteins created from these genes and hopefully the resistance mechanism.

Drug metabolism and toxicity is yet another area of great interest pertaining to DNA microarrays [57, 58]. Anticancer agents, just like other drugs, are metabolized by various enzymes in the human body. Additionally, toxic by-products from drugs can cause various degrees of end-organ damage. Metabolism and toxicity can vary from person to person. Utilizing DNA microarrays to understand the genetic variance in drug metabolism and toxicity has been a recent area of research. This area of research is commonly referred to as pharmacogenomics. The definition of pharmacogenomics is literally the understanding of genetic variance on drug pharmacokinetics and pharmacodynamics. By understanding these principles in individuals, the hope is to create individualized medicines for the treatment of their cancers. For instance, two individuals with the same type of cancer may need a different regimen or dose to treat their cancer based on their genetic differences in drug metabolism. Knowledge of this prior to dosing the medication may be able to reduce the amount of toxicity and increase the efficacy of the drug.

DNA microarrays are often touted as the future of anticancer research. Utilizing them to perform high-throughput processes allows for the rapid understanding of the genetic basis of tumor cells. Furthermore, they will help scientists to understand the subtle differences in various types of cancers. This combined with information on an individual's ability to metabolize a specific drug will assist in the development of personalized therapies [59]. The ultimate goal of this technology is to aid in "tailoring" therapy to an individual. This approach will lead to more effective treatments, with markedly reduced toxicity. These principles are the ultimate goals of anticancer therapy.

## 7 CURRENT CLASSES OF ANTICANCER AGENTS

Anticancer drug research has been going on for decades. Over the years, a vast array of anticancer drugs has been found. Many of these drugs work in a similar manner and belong to specific drug classes. The activities of specific drug classes will often stimulate further research to develop similar drugs. Knowledge of the mechanisms of action of current anticancer agents is vital to the creation of new agents. By evaluating the advantages and disadvantages of various available agents, work can be done to make more effective drugs.

Anticancer drugs are essentially drugs that work by killing cancerous cells. These agents can often destroy or damage normal healthy cells. The basic goal in anticancer drug research is to develop agents that are highly active in tumor cells and less active in healthy cells. Perhaps the best method to understand the scope of anticancer treatment is to look at the current classes of anticancer agents [60].

### 7.1 Alkylating Agents

Perhaps the first anticancer agents used were alkylating agents. Alkylating agents can be further divided into

**TABLE 1 Nitrogen Mustard Agents**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Chlorambucil | Chronic lymphocytic leukemia (CLL), non-Hodgkin lymphoma (NHL), waldenstrom's macroglobulinemia, polycythemia vera, ovarian cancer | Bone marrow suppression, gastrointestinal (GI) distress, central nervous system (CNS), hepatotoxicity |
| Cyclophosphamide | Leukemia, lymphoma, breast cancer, ovarian cancer | Bone marrow suppression, GI distress, alopecia, hemorrhagic cystitis |
| Ifosfamide | Lymphoma, breast cancer, sarcoma, lung cancer, ovarian cancer | Bone marrow suppression, GI distress, alopecia, hemorrhagic cystitis |
| Melphalan | Multiple myeloma, ovarian cancer, mesothelioma | Bone marrow suppression, GI distress, alopecia |

**TABLE 2 Nitrosureas**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Carmustine bis-chloroethylnitrosourea (BCNU) | Brain cancers, multiple myeloma, lymphoma | Bone marrow suppression, pulmonary toxicity, GI distress, hepatotoxicity |
| Streptozotocin | Islet cell cancer | Bone marrow suppression, GI distress |
| Lomustine *N*-(2-chloroethyl)-*N*′-cyclohexyl-*N*-nitrosourea (CCNU) | Brain cancers | Bone marrow suppression |

nitrogen mustard agents, nitrosureas, alkyl sulfonates, hydrazines, and aziridines. Platinum-containing agents are often included as alkylating agents as well. The alkylating agents are cytotoxic agents that work by alkylating DNA as their principle mechanism of action. Alkylating agents can react with various chemical groups on other cellular nucleophiles. By alkylating the cellular DNA, it becomes damaged. The DNA will subsequently become uncoiled and separates. This halts the DNA replication process and the cell can no longer divide.

Because malignant cells divide much more rapidly than normal cells, they undergo DNA replication more often than normal cells. Therefore, alkylating agents are useful as they damage the rapidly dividing cells. Unfortunately, the alkylating agents do not exclude all healthy cells. They will work on any cell that is undergoing DNA replication. Toxicities of the alkylating agents are typically seen in rapidly dividing cells such as the gastrointestinal tract, the reproductive system, and the bone marrow. Additionally, malignant cells can develop resistance to these drugs due to increased capability to repair DNA lesions. They can also develop resistance by selecting for cells that have decreased membrane permeability to alkylating agents. Resistance can also arise from the development of intracellular compounds that inactivate the alkylating agent before it can bind with the DNA.

Nitrogen mustard agents are often credited as being the first anticancer agents. During World War I, mustard gas was used as a chemical weapon. In the 1920s, mustard gas was dissolved in water and applied to superficial skin tumors. These tumors were noted to regress. This finding was quite astonishing initially but was abandoned initially. Then during World War II, the thought of using nitrogen mustard was revisited when an explosion of a ship containing mustard gas was shown to cause marrow and lymphoid hypoplasia in soldiers exposed to the blast. In the 1940s, Gilman and Philips performed the first anticancer clinical trial using nitrogen mustard in patients with lymphomas. The study had promising results, showing dramatic regression of the lymphomas, but these cancers were noted to grow back in many cases. Despite this, nitrogen mustard agents were discovered and the field of anticancer drug research was born.

Nitrogen mustard agents are the oldest modern anticancer agents. They are a class of alkylating agents. There are a number of nitrogen mustard agents that have been developed. Notable agents include cyclophosphamide, ifosfamide, and melphalan. A list of common nitrogen mustard agents is shown in Table 1. Although these agents are quite aged, they still are widely used today.

Nitrosureas are another important class of alklating agents. These agents do not typically have the same resistance patterns as other alkylating agents. Additionally, they are highly lipid soluble, which facilitates their transfer across the blood–brain barrier. Important nitrosureas include carmustine and streptozocin. A more extensive list is given in Table 2.

The platinum analogs are yet another important class of alkylating agents. These agents contain the inorganic metal platinum. Originally, these agents were found to

be alkylating agents when it was noted that they inhibited division of *Escherichia coli.* This group of drugs is not always considered as alkylating agents as their exact mechanism of action is still undefined. It is hypothesized that these agents work in the same way as alkylating agents by binding DNA by making various cross-linkages. This in effect inhibits DNA synthesis and causes cell death. These agents have also been seen to work synergistically with other chemotherapy agents (chemosensitizer) and with radiation therapy (radiosensitizer). Important agents included in this group are cisplatin, carboplatin, and oxaliplatin. These are explained in more detail in Table 3.

There are a number of other alkylating agents that have been discovered. These classes include the alkyl sulfonates, the hydrazines, and the aziridines. Please see Table 4 for more information on the drugs in these classes.

### 7.2 Antimetabolites

Cellular life and growth depends on various cellular metabolites. These metabolites include a variety of chemical compounds. Perhaps the most important of these compounds are the nucleic acids. As mentioned previously, cancerous cells grow and divide much more rapidly than normal cells. This frequent growth and division requires frequent synthesis of DNA. Nucleic acids and other cellular metabolites are required for DNA synthesis. By exploiting these links in the synthesis of DNA, anticancer agents can be developed. The class of antimetabolites does just this.

Most antimetabolites are compounds that show similarities to nucleotides or precursors to nucleic acids. They work by inhibiting normal DNA synthesis either by the production of abnormal nucleotides or by erroneous integration into the cellular DNA during replication. These agents can also work on the enzymes that are integral to nucleic acid synthesis. By inhibiting these enzymes, appropriate DNA synthesis cannot be achieved and further division cannot be achieved.

There are three major classes of antimetabolites. These include the folic acid antagonists, the purine analogs, and the pyrimidine analogs. The agents included in these classes are shown in Tables 5–7. The more widely used agents will be discussed below.

Methotrexate is a commonly used folic acid antagonist. For years, it has been known that folic acid is a necessary compound in cell growth and synthesis. Due to this, the idea of using an "antifolate" agent was pursued. Methotrexate was developed based on this concept. It works by binding to the active catalytic site of the dihydrofolate reductase (DHFR) enzyme. Inhibition of the DHFR enzyme inhibits the production

**TABLE 3 Platinum Agents**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Cisplatin | Lung cancer (small-cell and non-small-cell), ovarian cancer, lymphomas, sarcomas, germ cell tumors | Nephrotoxicity, peripheral neuropathy, nausea, ototoxicity, bone marrow suppression |
| Carboplatin | Ovarian cancer, lung cancer, head and neck cancer | Bone marrow suppression, GI distress, nephrotoxicity |
| Oxaliplatin | Colorectal cancer | Neuropathy, GI distress, bone marrow suppression, ototoxicity |

**TABLE 5 Folic Acid Antagonists**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Methotrexate | Leukemia, lymphoma, breast cancer, head and neck cancer, lung cancer | Bone marrow suppression, pulmonary toxicity, hepatotoxicity, nephrotoxicity, mucositis |
| Pemetrexed | Mesothelioma, non-small-cell lung cancer (NSCLC) | Bone marrow suppression, GI distress, stomatitis, anorexia, rash |

**TABLE 4 Other Alkylating Agents**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Busulfan | Chronic myelogenous leukemia (CML), CLL | Pulmonary toxicity, neurotoxicity, marrow toxicity, hepatotoxicity |
| Procarbazine | Hodgkin's lymphoma, brain cancers | Bone marrow suppression, GI distress, neurotoxicity |
| Temozolomide | Brain cancer, melanoma | Bone marrow suppression, GI distress |
| N,N′N′-triethylenethiophosphoramide (ThioTEPA) | Breast cancer, ovarian cancer, bladder cancer | Bone marrow suppression |

**TABLE 6 Purine Analogs**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Cladribine | Hairy cell leukemia | Fevers, bone marrow suppression |
| Mercaptopurine | Leukemia, lymphoma | Marrow suppression, hepatotoxicity, GI distress |
| Thioguanine | Leukemia, CML | Marrow suppression, hepatoxicity, GI distress |
| Fludarabine | CLL, acute leukemias, lymphomas | Marrow suppression, neurotoxicity, pulmonary toxicity |

**TABLE 7 Pyrimidine Analogs**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Cytarabine | Acute myelogenous leukemia (AML), lymphomas | Marrow suppression, mucositis, neurotoxicity (high dose), conjunctivitis (high dose), pulmonary edema |
| 5-Flurouracil (5-FU) | Colorectal cancer, pancreatic cancer | Marrow suppression, mucositis, neurotoxicity, rash |
| Capecitabine | Colorectal cancer, breast cancer | Hand and foot syndrome, marrow suppression, GI distress |
| Gemcitabine | Pancreatic cancer, NSCLC, bladder cancer, breast cancer | Marrow suppression, GI distress, fevers, hepatotoxicity |

of thymidylate, the purine nucleotides, serine, and methionine. These intracellular compounds are all integral to the formation of DNA, RNA, and critical cellular proteins. Decreased production of these compounds thus results in inhibited cellular division and growth. This effect is seen much more predominantly in rapidly dividing cancer cells.

Because the effects of methotrexate are seen in rapidly dividing cells, the most common adverse effects are related to bone marrow toxicity, gastrointestinal tract irritation, and mucositis. Cancer cells can become resistant to methotrexate through a variety of processes. Cases of decreased drug transport across the cellular membrane have been seen. Additionally, some cancer cells will be able to overcome methotrexate due to increased levels of the DHFR enzyme. Furthermore, cancer cells can sometimes develop a mutated form of the DHFR enzyme that has reduced affinity to the drug.

Purine and pyrimidine antagonists are also important antimetabolite drugs. Normal purines and pyrimidines are necessary for the production of DNA and RNA. By utilizing antagonists of these building blocks, DNA and RNA synthesis can be inhibited. Important pyrimidine antagonists include 5-fluorouracil (5-FU), capecitabine, cytarabine, and gemcitabine. Some purine antagonists include 6-mercaptopurine, fludarabine, and cladarabine. Because of its wide use and interesting mechanism of action, 5-FU warrants further discussion.

5-Flourouracil, or 5-FU, is a commonly used pyrimidine antagonist. Its utility is evident in its multiple mechanisms of action. The drug's main mechanism of action pertains to thymidylate synthase inhibition. The inhibition of this enzyme results in the decreased production of thymidine. Thymidine is a pyrmidine that is necessary for DNA replication. Furthermore, the drug is converted intracellularly to 5-flurouridine-5′-triphosphate (FUTP). During RNA synthesis, FUTP is incorperated into the RNA. This faulty integration causes problems with RNA processing and translation. In addition to this, the drug is also converted to 5-fluorodeoxyuridine-5′-triphosphate (FdUTP). This product is incorporated into DNA, causing inhibition of DNA synthesis. These multiple inhibitory effects on the thymidylate synthase enzyme, DNA, and RNA work together to cause cytotoxicity. Adverse effects seen with 5-FU and most purine and pyrimidine analogs include bone marrow toxicity, gastrointestinal tract irritation, and mucositis.

### 7.3 Plant Alkaloids

Natural products have held their place in drug discovery for years. Their contribution to the anticancer drug library is quite substantial. The vinca alkaloids, taxanes, epipodophyllotoxins, and comptothecins are all widely used, highly active classes of anticancer agents. Each class warrants further discussion.

The vinca alkaloids are drugs derived from the periwinkle family of plants. The vinca alkaloids include vinblastine, vincristine, vinorelbine, and vindesine. Vinblastine and vincristine are direct derivatives from the periwinkle plant *Vinca rosea.* Vinorelbine and vindesine are semisynthetic vinca alkaloids. These agents are displayed in Table 8. Their mechanisms of action of these agents are all quite similar. Their activity in various tumor types can differ, however.

The vinca alkaloids work by inhibition of tubulin polymerization. Inhibition of tubulin polymerization in turn inhibits the assembly of microtubules. Microtubules play an integral role in the maintenance of the cellular cytoskeleton. Furthermore, they are necessary elements in the development of the mitotic spindle during cellular division. Disruption of this system causes disruption of cell division during mitosis. This ultimately results in cell death. Of course, in malignant cells cell division is much

**TABLE 8 Vinca Alkaloids**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Vincristine | Lymphomas, acute leukemias | Vesicant, marrow suppression, neurotoxicity, GI distress, cardiovascular toxicity |
| Vinblastine | Hodgkin's lymphoma, NSCLC, breast cancer, testicular cancer | Vesicant, marrow suppression, hypertension, Raynaud's phenomenon |
| Vinorelbine | Breast cancer, NSCLC | Vesicant, marrow suppression, bronchospasm, cough |

more frequent. Therefore, these agents work much more effectively in cancerous cells.

Because of their effects on rapidly dividing cells, these agents are noted to cause bone marrow toxicity, alopecia, and gastrointestinal toxicity. The agent vincristine has also been shown to cause severe peripheral neuropathy and syndrome of inappropriate antidiuretic hormone hypersecretion (SIADH). Despite these adverse effects, these agents are commonly used in a variety of cancers, including non-small-cell lung cancer, breast cancer, leukemias, lymphomas, germ cell cancers, and multiple myeloma.

The taxanes are another important class of plant alkaloids. They include the agents paclitaxel and docetaxel. Both are products of the yew tree (genus *Taxus)*. They act in a similar manner to vinca alkaloids in that they are mitotic spindle inhibitors. Interestingly, the drugs do not work to inhibit the formation of the mitotic spindle. The drugs bind to microtubules and actually enhance tubulin polymerization. The enhanced polymerization occurs in the absence of compounds that are needed to make functional microtubule structures. The enhanced polymerization also inhibits normal microtubule breakdown, effectively locking the microtubules in place. The drug essentially causes erroneous formation of nonfunctional microtubule structures. These abnormal structures inhibit mitosis and ultimately cause cell death.

Because of their mitotic inhibition, the taxanes have substantial activity in a variety of cancers. Paclitaxel is the most widely used and is utilized in the treatment of a number of different solid tumors. Both agents do have substantial dose-limiting side effects. The side effects from paclitaxel are mostly related to its delivery vehicle, Cremaphor EL. Due to this a large amount of research is being done to find an alternative vehicle. This is further discussed in the drug formulation and delivery chapter. Please see Table 9 for more information on adverse effects and the tumor types treated with the taxanes.

**TABLE 9 Taxanes**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Paclitaxel | NSCLC, breast cancer, ovarian cancer, head and neck cancer | Hypersensitivity reactions, marrow suppression, mucositis, alopecia, peripheral neuropathy |
| Docetaxel | Breast cancer, ovarian cancer, NSCLC | Hypersensitivity, fluid retention, marrow suppression, peripheral neuropathy |

**TABLE 10 Camptothecins**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Topotecan | Ovarian cancer, lung cancer | Marrow suppression, mucositis, GI distress, alopecia |
| Irinotecan | Colorectal cancer | Diarrhea, marrow suppression, alopecia, GI distress, pulmonary toxicity |

The camptothecins are yet another class of plant alkaloids in use today. They are derived from the *C. acuminate* tree. Agents include topotecan, irinotecan, camptothecin, and rubitecan. The drugs have a similar mechanism of action that involves the inhibition of the enzyme topoisomerase I. This enzyme is integral in the normal breakdown and religation of the phosphodiester backbone of DNA strands. Inhibition of this enzyme, therefore, inhibits DNA synthesis and damages DNA. The damaged DNA causes apoptosis and cell death. These effects are especially noted in rapidly dividing cells such as cancer but can also be noted to have effects in the bone marrow and the gastrointestinal tract. The adverse effects and cancers treated with these agents are noted in Table 10.

The epipodophyllotoxins are anticancer agents derived from the root of the mayapple plant (*Podophyllum peltatum*). Included in this class are the compounds etoposide and teniposide. These agents are similar in their mechanism of action. They work by inhibiting topoisomerase II. Similar to topoisomerase I inhibition, the inhibition of topoisomerase II causes DNA damage. This damage is mediated by the strand breakage caused by complexes of the drug, the DNA, and the topoisomerase enzyme. This arrests cell division and causes cell death. This effect is once again enhanced in rapidly dividing cells, including cancer cells. Please see Table 11 for more information regarding the side effects and cancers treated with these drugs.

**TABLE 11 Epipodophyllotoxins**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Etoposide | Ewing's sarcoma, lung cancer, brain cancer, lymphoma, testicular cancer | Marrow suppression, alopecia, hypersensitivity, GI distress, mucositis, hypotension |
| Teniposide | Acute lymphocytic leukemia (ALL) | Marrow suppression, alopecia |

### 7.4 Anticancer Antibiotics

Many drug discoveries occur when researching other diseases. The search for antimicrobials has yielded several useful anticancer agents. As microbes are often the source for many antibiotics, they often serve as natural sources for anticancer agents. Many microbes have defense mechanisms that work in a manner similar to the desired effects of some anticancer agents. These defense mechanisms have been researched and can be successfully exploited to destroy cancerous cells.

Perhaps the most famous class of anticancer antibiotics is the anthracyclines. The anthracycline antibiotics are compounds derived from the microbe *Streptomyces peucetius*. Agents derived from this microbe include doxorubicin, daunorubicin, idarubicin, epirubicin, and mitoxantrone. The agents included in this group have been utilized as anticancer agents for many years. They are used in a very wide variety of cancers. The reason for this is likely due to their array of mechanisms of action.

The anthracyclines have a number of mechanisms to destroy cancerous cells. First of all, these compounds have a high affinity to DNA/RNA and will intercalate between base pairs. This intercalation causes disruption of DNA and RNA synthesis. Like many other drugs that interrupt DNA and RNA synthesis, this action causes cell death. In addition to this primary mechanism, anthracyclines generate iron-dependent, enzyme-mediated oxygen free radicals. These free radicals wreak havoc on the cell by damaging DNA and cell membranes. The anthracyclines will also damage the cellular membrane by binding to it and altering fluidity and ion transport. Finally, anthracyclines have the ability to inhibit topoisomerase II. Their inhibition of this enzyme causes halting of the enzymes normal progression. This mechanism essentially causes the complex to stabilize before it can reseal the DNA double helix during replication. This effectively terminates DNA synthesis and thus causes cell death.

By utilizing several different cytotoxic mechanisms, the anthracyclines hold their place as some of the most useful chemotherapeutics to date. Doxorubicin is perhaps the most widely used, with proven clinical activity in breast, endometrial, testicular, ovarian, lung, and stomach cancer, just to name a few. The drug is also quite useful in a number of hematologic malignancies. The side effect profile of these agents can vary slightly with each drug, but they all include some element of bone marrow toxicity, mucositis, and cardiotoxicity. Detailed information on the individual side effect profiles and clinical uses for the anthracyclines is shown in Table 12.

**TABLE 12 Anthracyclines**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Daunorubicin | AML, ALL | Marrow suppression, mucositis, alopecia, cardiovascular toxicity, vesicant |
| Doxorubicin | Leukemia, lymphoma, bladder cancer, breast cancer, stomach cancer, lung cancer, ovarian cancer, sarcomas, multiple myeloma, | Marrow suppression, mucositis, alopecia, cardiovascular toxicity, vesicant |
| Idarubicin | AML | Marrow suppression, minimal cardiotoxicity |
| Epirubicin | Breast cancer, ovarian cancer, lung cancer, gastric cancer, lymphomas | Marrow suppression, cardiotoxic |
| Mitoxantrone | Breast cancer, AML, lymphoma | Marrow suppression, cardiotoxic, blue-colored urine, sclera, nails |

There are a number of other antitumor antibiotics that are used in clinical practice today. These agents are similar to the anthracyclines in that they work by inhibiting normal DNA and RNA synthesis. They include mitoxantrone, dactinomycin, mitomycin, and bleomycin. The clinical uses and side effects of these agents are shown in Table 13.

### 7.5 Hormonal Agents

Breast and prostate cancer are two very common and lethal cancers. As these cancers are typically found in a specific sex, it is no surprise that the sex hormones play a role in their proliferation. If the hormones play a role in proliferation, they can also be a key to the cancer's

**TABLE 13 Other Antitumor Antibiotics**

| Drug | Uses | Major Toxicities |
|---|---|---|
| Bleomycin | Hodgkin's lymphoma, testicular cancer | Pulmonary toxicity, Raynaud's syndrome, skin toxicity |
| Mitomycin | Esophageal cancer, breast cancer, bladder cancer | Marrow suppression, vesicant, pulmonary toxicity, cardiac toxicity, hemolytic uremic syndrome |
| Actinomycin | Wilm's tumor, rhabdomyosarcoma | Marrow suppression, GI distress, mucositis, vesicant, alopecia |
| Mitoxantrone | Breast cancer, AML, lymphoma | Marrow suppression, cardiotoxic, blue-colored urine, sclera, nails |

demise. At the present time, there has been a great deal of research in "antihormone" agents that can be utilized to treat breast and prostate cancer. The plan of blocking the hormonal growth stimulus has proven to be a useful weapon in the anticancer arsenal. The agents currently used can be divided into the classes of selective estrogen receptor modulators, aromatase inhibitors, androgen antagonists, and gonadotropin-releasing hormone agonists.

### 7.6 Selective Estrogen Receptor Modulators

The selective estrogen receptor modulators (SERMs) are a class of drugs that exhibit effects on human estrogen receptors [61]. These agents are quite interesting in regards to their ability to have both agonistic and antagonistic effects on estrogen receptors depending on the tissue affected. Estrogen has a number of effects on a number of normal tissues. The fact that breast cancer is often noted to have its growth modulated by the presence of estrogen makes this class of drug particularly interesting. The SERM of most interest and utility as an anticancer agent today is tamoxifen.

Tamoxifen is a SERM with mixed estrogen receptor agonism and antagonism in various tissues. Most importantly tamoxifen has profound estrogen receptor antagonism in breast tissue. The drug is taken orally and is converted in the liver to its active form. The active form of the agent then competitively binds to estrogen receptors in the target tissues and, more importantly, estrogen-receptor-positive tumors. Once it has bound to the receptor, the drug produces a nuclear complex that inhibits the effects of estrogen on the tissues. One of these inhibitory effects is to decrease DNA synthesis. The decreased DNA synthesis results in the halt of the cell cycle. The drug is often termed cytostatic rather than cytotoxic due to these effects.

Tamoxifen is generally well tolerated due to its "estrogen"-limited mechanism of action. In contrast to its estrogen antagonism tumors, it works as a weak agonist in bone. This makes it a useful agent in the treatment of osteoporosis. However, the drug does have some notable side effects. The major concern when using the drug is related to its partial agonism in endometrial tissue. This partial agonism leads to an increased incidence of abnormal uterine bleeding and in some cases an increased risk for endometrial cancer. Tamoxifen also increases the risk for venous thromboembolism and hot flashes.

In spite of its side effects, tamoxifen remains one of the most widely used agents for estrogen-receptor-positive tumors. Its use has stimulated a great deal of research in the area of antihormonal therapies. Other SERMs continue to be investigated and compared to tamoxifen to determine if they are superior. For the time being, tamoxifen remains the most useful SERM in regards to breast cancer treatment. Development of tissue-specific SERMs that exhibit beneficial effects in bone and the cardiovascular system, while continuing their antagonism in tumor tissue, is the focus of current research.

### 7.7 Aromatase Inhibitors

Other methods of blocking the effects of estrogen on tumor cells have given birth to the aromatase inhibitors. The production of estrogen in the human body is mediated by the enzyme aromatase. This enzyme works to convert androgens into estrogens. As noted earlier, estrogen enhances DNA synthesis in many tissues, including estrogen-receptor-positive tumors. By inhibiting the production of estrogen in the body, this DNA synthesis will also be decreased. In tumors, this is particularly useful as it causes the tumor cells to have arrested development. The aromatase inhibitors work in various ways to inhibit the aromatase enzyme. The agents included in this class are anastrozole, aminoglutethimide, letrozole, and exemestane. Anastrozole and letrozole act reversibly on the aromatase enzyme while exemestane binds irreversibly.

When compared to tamoxifen in clinical trials, aromatase inhibitors have been shown to be more effective. Perhaps this is because estradiol has a higher affinity to estrogen receptors than tamoxifen. This means that any amount of estradiol in the body can limit the effectiveness of tamoxifen. From this information it appears that it is quite important to decrease the amount of

estrogens circulating in the body as much as possible. The aromatase inhibitors allow for this to occur. The aromatase inhibitors have been shown to be slightly superior to tamoxifen in trials involving postmenopausal patients.

The aromatase inhibitors are also well tolerated. Their side effect profile is similar to that of the symptoms of menopause due to the loss of estrogen. Some common side effects seen with all aromatase inhibitors include hot flushes, fatigue, arthralgias, and headaches. Despite this side effect profile, these agents will continue to be important agents in estrogen-receptor-positive cancers.

### 7.8 Androgen Antagonists

Just as the estrogen plays an important role in cell growth in estrogen-receptor-positive cancers, androgens play an important role in androgen-receptor-positive tumors. Prostate cancer is a type of cancer that exhibits androgen-related growth. Inhibition of the androgen receptor in prostate cancer results in slowed cell growth. The agents flutamide and bicalutamide are both antiandrogen agents that are utilized in prostate cancer due to this effect. They are not cytotoxic, but they are useful in slowing the growth of the disease. The drugs are fairly well tolerated but commonly cause hot flushes, nausea, and mild elevations in transaminases.

### 7.9 Gonadotropin-Releasing Hormone Agonists

Gonadotropin-releasing hormone agonists (GnRH agonists) serve as another method to disrupt androgen synthesis. Gosrelin and leuprolide are both synthetically produced analogs of GnRHs. These drugs work by causing a "superagonist" effect on the pituitary. This in turn causes downregulation of the production of lutenizing hormone (LH) and follicle-stimulating hormone (FSH). These hormones are responsible for the production of the androgens. Once again, these agents are cytostatic agents. They are useful in slowing the progression of prostate cancers. Due to this they are widely used in advanced prostate cancer. Their side effect profile includes hot flushes, gynecomastia, and impotence.

### 7.10 Molecular Targeted Therapies

The evolution of biomedical research has expanded our understanding of cellular biology. As we learn about normal cells, we are able to see the differences present in malignant cells. In particular, recent research has produced knowledge of the intricate cellular signaling pathway in a number of tissue types. The signaling pathways in many tumors have also been analyzed. These signaling pathways are vital for the control of cell growth, division, differentiation, metabolism, and apoptosis. By targeting these pathways, these cellular processes can be modulated or even stopped. The era of molecular medicine has risen from this concept. Oncology has been a significant beneficiary from this area of research.

The protein kinases are a class of enzymes that play an integral role in cellular differentiation, proliferation, and regulation [62]. These enzymes can be abnormally regulated in some forms of cancer. Included in the class of protein kinases are the growth-related kinases. Perhaps the most interesting growth-related kinases are the tyrosine kinases. These kinases include epidermal growth factor receptor (EGFR), vascular endothelial growth factor (VEGF), and platelet-derived growth factor (PDGF). Inhibition of these kinases can lead to suppressed cell growth. It is no surprise that tyrosine kinase inhibitors have been heavily researched in recent years as potential anticancer agents.

There are a number of receptor and nonreceptor tyrosine kinase inhibitors that have been developed and that are in current development. All of these drugs work through inhibitory mechanisms on the tyrosine kinase enzyme. Some may target only one tyrosine kinase, while others will target several [63]. Perhaps the best way to understand these molecules is to discuss a few of them.

### 7.11 Imatinib

One of the most well-known tyrosine kinase inhibitors is imatinib (Gleevec). This tyrosine kinase inhibitor works by inhibiting the tyrosine kinase domain of the Bcr-Abl oncoprotein, thus preventing phosphorylation of the kinase substrate by ATP. The Bcr-Abl oncoprotein is a product of the Philadelphia chromosome translocation, t(9:22). This translocation is commonly seen in chronic myelogenous leukemia (CML) and other leukemias. The Bcr-Abl oncoprotein activates mitogenic and antiapoptotic pathways, thus causing abnormal cell growth and virtual immortality. Inhibition of this oncoprotein has proven to be a successful way to halt these processes.

Soon after the Bcr-Abl product was found, the search for an inhibitor was started. Imatinib was developed by chemists by utilizing high-throughput screening of chemical libraries. Ultimately, a lead compound was found and imatinib was derived from this. The drug is credited for drastically changing the therapy for CML.

Interestingly, imatinib has been shown to have activity in gastrointestinal stromal tumors (GISTs) as well. This is due to the presence of the *c-kit* tyrosine kinase mutation in these tumors. In addition to inhibition of

the Bcr-Abl product, imatinib has been found to be a selective mast/stem cell growth factor receptor (KIT) tyrosine kinase inhibitor. This multikinase inhibition allows for the agent to be useful in multiple types of cancer. This quality is seen in several protein kinase inhibitors.

Molecular targeted agents are typically well tolerated due to their specific mechanism of action. Imatinib is no exception to this rule and is usually well tolerated. Side effects include as nausea, myalgias, edema, and a rash.

### 7.12 Gefitinib and Erlotinib

Growth factor receptors are a group of tyrosine kinases that regulate various cellular growth mechanisms. There are a number of different types of this receptor. One of these is the epidermal growth factor receptor (EGFR). This receptor is commonly overexpressed in a variety of cancers, notably breast, colon, and lung cancer. Activation of EGFR causes the Ras signal transduction pathway, which causes an antiapoptotic response. This leads to uninhibited cell growth, unregulated proliferation, increased angiogenesis, stimulation of cell invasion, and metastasis.
